## Preface

With publication of this new eighth edition of Rosenau, which has come to be regarded as a classic in its field, we are retitling it in the belief that the word *Hygiene* no longer connotes its range, and that this new title, *Preventive Medicine and Public Health*, will more adequately indicate the scope and purposes of the book which are unchanged.

The subject matter has been critically reviewed and revised in the light of recent findings by each contributing author whose name appears with his section. The editor is responsible for the remainder. To bring the book up to date, 634 pages, or 44 per cent, of the text in the previous (1951) edition have been rewritten either completely or in part. Recent figures have been incorporated in the text and statistical tables. Where recent contributions have advanced knowledge or concepts during the past five years selected references have been added to document the work and afford the reader opportunity to pick up the thread of current investigations or changes. The index has been greatly enlarged and it is more detailed in its coverage.

To understand the selection of subject matter it is necessary to know the past history of this book. When the first edition was published in 1913, Dr. Milton J. Rosenau, then Professor of Preventive Medicine at the Harvard Medical School, opened his preface with the following words: "This book has been written in response to a demand for a treatise based upon modern progress in hygiene and sanitation. The work is planned to include those fields of the medical and related sciences which form the foundation of public health work. So far as I know no other book on the subject covers the broad field considered in this volume. The progress in hygiene and sanitation has been so rapid that the subject of preventive medicine has become a specialty, and its scope has become so broad that the question throughout the making of this book has been rather what to leave out than what to include. The facts here brought together are widely scattered in the literature and many of them difficult of access; they have been collected for the student of medicine and the physician, as well as those engaged in sanitary engineering or public health work."

In five subsequent editions, with the help of collaborators, Dr. Rosenau kept up with the progress in this rapidly developing field. His sixth and last edition was published in 1935. Approaching the end of a rich and fruitful career, he thought that it was time the burden be passed on to some younger colleague. So it was that this textbook came under the present editorial supervision and the seventh edition appeared in 1951. In the sixteen years that had elapsed since publication of the sixth edition by Rosenau there had been remarkable scientific and practical advances in the field of public health and preventive medicine. While it was possible to retain some parts of the old text with little change, it was necessary to revise or rewrite large parts and to introduce much new material. Furthermore, to fulfill its function adequately it was necessary to enlist collaboration with a wider range of specialists. So the seventh edition became a joint contribution of some 27 authors. Inevitably, there was some overlapping of subject matter, but effort was made to

## PREFACE

reduce this to a desirable minimum by cross references in the text, emphasizing interrelationships.

Grateful acknowledgement is made of the assistance rendered by collaborators in bringing about this revision. I am immeasurably indebted to Mrs. Margaret R. McConnell whose efficient editorial assistance has made this edition possible. I wish also to thank Mrs. Hermine Bird for reading proof and checking references. Finally, it is a pleasure to again express my appreciation to Appleton-Century-Crofts, Inc., particularly to Mr. George A. McDermott and his staff, for constructive interest and editorial guidance.

. KENNETH F. MAXCY

# PREVENTION OF COMMUNICABLE DISEASES

## 1

### CONTAGIOUS DISEASES SPREAD LARGELY FROM THE MOUTH AND NOSE

The beginnings of hygiene can be traced back to antiquity in the sanitary laws of the Hebrews. Preventive medicine began with the first primitive idea of contagion. Even in the time when epidemics were explained as due to the wrath of the gods or visitations of evil spirits, it was observed that certain illnesses apparently spread from person to person. Gradually, the idea of contagiousness was associated with a number of diseases. Fracastorius, in his book *De Contagione*, published in 1554, proposed a classification of diseases into those which were contagious and those which were not. For three centuries following this publication the medical profession was divided into two camps: the non-contagionists, who believed that the causative agents of epidemic disease were inanimate and gaseous in nature and associated with emanations from decomposing organic matter, effluvia and miasma; and the much smaller group, the contagionists, who identified contagiousness with germs of some kind.

Looking backward, this confusion is understandable. That some diseases were contagious was fairly obvious, but some apparently arose spontaneously without a traceable source. The confusion was finally resolved in the latter part of the nineteenth century by the work of Pasteur, Koch, and their followers. The causative relationship of specific micro-organisms for one after another of the infectious diseases was established and the part played by carriers, missed cases, common water and food supplies, arthropod vectors, and animal reservoirs in transmission was gradually elucidated.

With these advances in knowledge came the vision of the possibilities of prevention of disease by community measures. Health departments were organized very largely for the purpose of controlling the spread of communicable diseases by isolation and quarantine, sanitation, immunization and diagnostic services. It was not until after the turn of this century that they became concerned with the broader aspects of preventive medicine. It is appropriate, therefore, that this book begin with a discussion of communicable diseases. Furthermore, it is also appropriate, since our interest is primarily in prevention, to classify these diseases on the basis of the principal mode of transmission. The first to be considered and most important from the point of view of the mortality and morbidity which they cause the world over, are those contagious diseases spread largely by discharges from the nose and mouth. While alike insofar as they are caused by microparasites which enter and leave the human host through the respiratory tract, they differ in many ways. These invaders are of various genera and species: viruses, rickettsiae, bacteria and fungi. There is a wide range in their potential pathogenicity both for the individual and

for the community. Each has its own distinct clinical, pathological and epidemiological pattern, determined by the peculiar biological relationships of the specific causative microparasitic species or race to the human host on the one hand and to environmental conditions on the other. With each, understanding of these relationships is essential to effective measures of control. Such generalizations as can be drawn regarding methods directed toward reduction in the spread of respiratory or air-borne infections will be discussed in a later chapter.

## SMALLPOX

(*Variola*)

Smallpox is an acute exanthematous fever. Onset is sudden with pyrexia, headache, backache, pains in the limbs, vomiting. In severe cases prodromal rashes, erythematous or petechial, may appear. On the second to the fifth day characteristic eruption begins to develop, the temperature falls, and the constitutional reaction abates. The eruption is general and may occur on all parts of the skin and exposed mucous membranes. It comes out in a single crop as maculopapules, which develop into vesicles, and these into pustules which dry and crust. Pocks are most numerous on the face, forearms, wrists, palms of the hands, and soles of the feet. During the pustular stage of the eruption the temperature may rise again. Four clinical types are recognized: (1) discrete, (2) confluent, (3) hemorrhagic (including the highly fatal hemorrhagic pustular form and the uniformly fatal purpuric form), and (4) modified.

The period of incubation has a mean of 12 days, although variations from 7 to 21 days have been noted. Usually, 14 days elapse between exposure and appearance of the eruption.

Two types are now recognized. The classical or true smallpox is called *variola major*. Its severity varies from time to time and in different geographical areas, the case fatality rate ranging from about 5 per cent to 40 per cent or more. During the epidemic at Minneapolis, affecting 571 persons, Sweitzer and Ikeda (1927) reported the following death rates in the clinical varieties observed: among 225 cases with discrete eruption 14, or 6 per cent, died; among 151 cases with confluent eruption 68, or 45 per cent, died; among 144 cases of the hemorrhagic type 113, or 78 per cent, died; of 51 cases classified as *variola purpurica* all died.

Since the latter part of the nineteenth century a mild type of smallpox has been described under many names—*alastrim*, *Katfir-pox*, *amaas*, *milk-pox*. It is now recognized as *variola minor* (Marsden, 1948). It may closely simulate chickenpox, from which it can be differentiated at times only by laboratory procedures (see page 24). It is almost never a cause of death by itself.

Recovery from a clinical attack of smallpox is followed by an immunity that is usually lifelong. Second attacks in the same individual are extremely rare.\* *Variola major* affords immunity to *variola minor* and vice versa.

Prevalence. It is difficult for us now to realize that smallpox was once as common as measles and much more fatal. Many of those who recovered were disfigured for life, left blind, or left with some other serious consequence of the disease. For

\* Jenner mentions "the lady of Mr. Gwinnett, who has had smallpox five times," in *Bacon's Life of Jenner*, vol. II, page 265. Louis XV of France died of a second attack.

centuries, smallpox was one of the greatest scourges. It depopulated cities and exterminated tribes. In Europe alone, where its ravages were comparatively slight, it killed hundreds of thousands yearly. In the eighteenth century, of which we have the best records, almost everybody had it before he grew up. Parents often exposed their children to the disease in order to be through with it, just as they now sometimes do with the minor contagious diseases. In China, a mother does not number among her children those who have not yet had smallpox, because she well knows how uncertain will be their stay in the family.

Smallpox was introduced into the Western Hemisphere by the Spaniards about 15 years after the discovery of America. In Mexico, within a short period, 3,500,000 persons are said to have died of the disease. Catlin in 1841 stated that of 12,000,000 American Indians, 6,000,000 fell victims to smallpox. In Iceland, in 1707, 18,000 perished out of a population of 50,000; that is, smallpox killed 36 per cent of the total population in one year.

Up to the end of the nineteenth century, true virulent smallpox (*variola major*) was the prevalent type in most countries of the world. It is still propagated in limited geographic areas of Asia, Africa and South America. Gradually, however, *alastrim* (*variola minor*) has become more and more widely disseminated (Hedrich, 1936). According to Chapin and Smith (1932) it made its appearance in the United States at about the time of the Spanish-American War, presumably being introduced by way of the West Indies from Africa. In most of the years since, while the number of reported cases has been large, the fatality rate has ranged from 0.69 to 0.29 per cent (Dauer, 1940). From time to time, however, in this country as in others this experience has been punctuated by the occurrence of sharp outbreaks characterized by a high fatality rate. These have originated through importation. They are usually traced to an unrecognized case recently arrived from another country. For example, the epidemic of 1924-1925 was traced to two tramps and a boy who were infected with malignant smallpox in Winnipeg, Manitoba, in January, 1924. They carried the disease to Duluth, Minnesota, to Detroit, Michigan, and to New Britain, Connecticut. From these centers it radiated, causing 74,000 cases and 1,270 deaths. More recently, an outbreak of *variola major* in the State of Washington was traced to the arrival of a ship from the Orient with cases of malignant smallpox on board (Palmquist, 1947). In the same year a virulent strain was introduced into New York City by a traveler coming from Mexico (Weinstein, 1947). Similarly instructive is the outbreak in Scotland in 1942 (Macgregor and Peters, 1942).

With advance in public health administration and preventive medicine, conditions are now unfavorable to continuous propagation of smallpox in many countries (WHO, 1951). No outbreaks have been reported from Pacific Oceania for the past decade. The continent of Europe, with the exception of Portugal, shelters no endemic focus but is repeatedly and constantly threatened with importations of the disease by land, sea and air travelers. The same may be said for the British Isles, Canada and the United States. In this latter country, the number of reported cases has decreased from 48,907 in 1930 to 39 in 1950.

**Pathogenesis.** Downie (1951) has recently reviewed evidence on which the present day concepts of pathogenesis of smallpox are based. It is still not possible to

## DISEASES SPREAD FROM THE MOUTH AND NOSE

give a detailed account of the course of events which follow human infection with the virus of smallpox. Nevertheless, the outline of the story seems fairly clear.

Table 1-1. Smallpox in the United States, 1900-1950

Year	Number of Cases *	Number of Deaths *	Case Fatality Rate Per Cent	Year	Number of Cases *	Number of Deaths *	Case Fatality Rate Per Cent

\* Data from 1900 to 1928 from Chapin, C. V., and Smith, J., *J. Prev. Med.*, 6:273, 1932. Data from 1929 to 1939 from Dauer, C. C., *Pub. Health Rep.*, 55:2303, Table 1, 1940. Data from 1940 to 1950 from Public Health Reports.

The site of entry of the virus is to the tissues of the upper respiratory tract. At most, only a minimal or closed lesion occurs in the mucous membrane, and the virus quickly passes to lymphatic glands and by blood stream to internal organs. Progressive infection of cells in these organs, with multiplication of the virus, takes place during the incubation period. Toward the end of this period or at the onset of illness there is an overflow of virus into the blood stream (viremia). The transient viremia leads to widespread infection of the skin, mucous membranes and other tissues, although lesions do not become apparent in the skin for a further two to three days. As these lesions break down, liberating virus on the surface, the patient becomes infective for others. The immune response with formation of antibodies follows. The rapidity and extent of the antibody formation determines the extent of the rash and the severity of the disease. The maturation of the eruption proceeds after the antibodies have appeared and is secondary to the destruction of cells infected in the first few days of illness. Persons who die in the later pustular stage of the eruption may have a high titer of antibody in their sera; in such persons death is due to the late effects of earlier virus activity or to some complicating disability or

infection. Antibodies persist at a high level for some years after clinical recovery. Rarely, there are individuals (usually partially protected by previous vaccination) in whom the mobilization of antibodies is so rapid that they have a very brief illness without eruption, *variola sine eruptione*. Transplacental infection of a fetus in utero of an expectant mother who develops the disease may occur as a sequel of the viremia. Whether an attack of smallpox in the early months of pregnancy may be a source of fetal defects, as in rubella, is unknown.

**Mode of Transmission.** Smallpox is preeminently a contagious disease of man. It is propagated by some form of human contact, direct or indirect, from an infected to a susceptible individual. The virus makes its exit from the infected host through the lesions in the mucous membrane of the mouth and pharynx and through the lesions of the skin. While most infectious during the early eruptive stage, the period of communicability is regarded as lasting from the onset of illness to the complete exfoliation of crusts and scabs. Direct transmission for short distances may occur through projection of droplets or droplet nuclei from the upper respiratory tract of an infected host. Indirect transmission takes place through contamination of bed clothes and other articles in the patient's surroundings. Dried infective material may be resuspended as air-borne dust particles (Downie and Dumbell, 1947). Ordinarily the range of infectiousness is limited to the vicinity of the infected individual. Instances have been reported in which an apparently healthy person conveyed the virus, but subclinical or inapparent infections are comparatively rare.

Smallpox is occasionally transmitted by accidental inoculation of the abraded skin of a susceptible individual with infectious material from a patient. The protopapules (of Ricketts), usually situated on the face, are recognized on account of the larger size and more advanced development than the remaining element of the general eruption, which they commonly precede by several days.

**Variola Virus.** Three major types of the variola-vaccinia virus group are recognized: (1) *variola major* or smallpox, (2) *variola minor* or alastrim, and (3) vaccinia or cowpox. They are closely related and have essentially the same physical characteristics and properties, yet they are readily distinguished by the reaction which they produce in man and in experimental animals. The first two can, by persistent effort, be transformed into the third by animal passage.

In suspensions prepared from tissues infected with variola-vaccinia virus small granules can be demonstrated, known variously as elementary bodies, E.B.'s and Paschen bodies, which have been shown to be aggregates of virus molecules.

Guarnieri in 1892 described the bodies which now bear his name in the deep epithelial cells of the skin in cowpox and smallpox, as well as in the epithelial cells of the cornea of rabbits. These intracellular inclusion bodies are now accepted as being quite specific. They can be demonstrated in all types of infection with the variola-vaccinia virus. They are probably masses of elementary bodies held together by a matrix.

Variola virus is quite stable. In dried state it may retain its viability for some time. Thus, Downie and Dumbell (1947) found that desquamated crusts which were stored for a year in a stopped bottle at room temperature contained viable virus. This stability facilitates diagnostic studies, since material for examination can be shipped without refrigeration. On the other hand, infectivity of variolous crusts suspended in Locke's solution is destroyed by heating at 55° C for 20 minutes or at

37° C for 24 hours. The virus is quite resistant to desiccation and cold. It is rapidly destroyed by exposure to sunlight or ultraviolet rays. It is not so easily killed as are nonsporing bacteria by many of the chemical germicides in common use.

**Laboratory Diagnosis.** Laboratory methods are invaluable in confirming the clinical diagnosis of smallpox. This may be accomplished by identification of the virus or its antigens in material derived from cutaneous lesions early in the course of the disease or the demonstration of specific antibodies in the serum obtained late in the disease or during convalescence. Antibodies may be demonstrated by various techniques: by complement fixation, by tests for inhibition of virus hemagglutinin, or by various types of tests to measure the power of serum to inhibit or neutralize the infectivity of the virus. The procedures generally employed are given in detail by Parker (1948). In brief, those found most useful are the following:

1. Smears are obtained by scraping the base of papules or vesicles and transferring the material to stained glass slides. The preparation is fixed, stained and examined with a microscope for elementary bodies.

2. Material for test is obtained by washing the scrapings from the base of the papule with a scalpel into a small quantity of physiologic saline solution or by a preparation of vesicular or pustular fluid collected in capillary tubes. A 10- or 11-day-old chick embryo is inoculated with a suspension of suspected material dropped onto the surface of the chorioallantoic membrane. The egg is incubated for three days and then examined for characteristic lesions produced by variola. To confirm the identification the infected membrane should be suspended in saline solution for further passage in the chick embryo and for inoculation of rabbit skin and rabbit cornea (the Paul reaction). The virus originating in man giving discrete lesions on the chorioallantoic membrane of chicks, producing keratitis in rabbits with Guarnieri bodies in corneal cells and producing inconsequential or no lesions on rabbit skin may be considered variola.

3. Variola antigen in a lesion may be identified in a complement-fixation test using hyperimmune rabbit serum as a test reagent. The antigen is prepared by extracting smears of pustule fluid or crusts.

4. Using variola antigen prepared by egg culture, serum from the patient is tested for complement-fixing antibodies early and late in the course of the disease.

Downie, McCarthy and MacDonald (1952) assessed the value of these four methods of diagnosis in an epidemic of alastrim. Specimens were received from 154 patients and in 87 the diagnosis of alastrim was made by one or more tests. They point out that the clinician should not consider diagnosis of alastrim to have been excluded when he receives a negative report on stained smears. Both the complement-fixation test for alastrim antigen and the egg culture method are extremely reliable, provided there is sufficient material for examination. A test for specific antigen can provide a result within a day or two of taking the specimen, while egg culture, although slow, is probably the more conclusive. Complement-fixation tests for antibodies in the patient's serum are of value only when the patient has been ill for some 10 days and are used chiefly in atypical missed cases when the lesions have healed.

**Treatment.** None of the recently developed antibiotic drugs has been demonstrated by critical trial to be effective in the treatment of smallpox virus infection.

They may be of some value in suppressing secondary bacterial invasions which may complicate the clinical course of the disease.

**Prevention and Control.** From the point of view of the individual, there is only one way to prevent smallpox, and that is through vaccination. The method is logical, specific, sensible, and satisfactory.

There is only one way to prevent the epidemic spread of smallpox in a community and that is by maintaining at all times a high degree of immunity through routine vaccination of all infants and revaccination of young children on entering school. The entire population should be revaccinated when the disease appears in severe form.

Control of spread in a community in which there is a considerable proportion of susceptible persons depends primarily upon the early recognition, reporting, and isolation of the first case or cases to appear. All who have been in contact with a case since the onset of symptoms should be detained pending establishment of immunity. They should be vaccinated with virus of full potency and kept under daily observation until the reaction has passed its maximum intensity, if the vaccination has been performed within 24 hours of first exposure and the strain of smallpox was of *variola minor* type; otherwise, for 16 days from the date of last exposure. To erect a barrier of immunes, as many persons as possible living or working in the environment of each case should be vaccinated.

Since the virus is an obligate human parasite and can survive only a short time under conditions outside the human body, attempt should be made to trace the source of every case. The infection must have originated from contact with an individual who has had the disease in recognized or unrecognized form. Particularly with alastrim is it necessary to investigate cases of supposed chickenpox associated in time or place, and to review carefully for error of diagnosis.

## VACCINATION AND SMALLPOX

**Historical Note.** The credit of giving vaccination to the world is due to Jenner (1798), who through logical and scientific methods proved that a person who has had the mild disease cowpox enjoys protection against the serious disease smallpox. This fact had been known to some of the farmers and folk of England for a long time. But it was Jenner who first put this vague belief upon a scientific basis.

Jenner made his crucial experiment May 14, 1796, when he transferred vaccine material from the hand of a dairy maid (Sarah Nelms), who was infected with cowpox and who had scratched her hand with a thorn, to the arm of a boy about eight years old (James Phipps). A typical take followed. On July 1 Jenner inoculated the boy with variolous matter, but no disease followed. Several months later he again inoculated the boy, with the same results.

In addition to such direct experimental proof, Jenner inoculated smallpox matter into 10 persons who had at some previous time contracted cowpox and found that they were resistant to smallpox. Jenner himself was inoculated when a boy. The question of "inoculation" (with smallpox) as contrasted with "vaccination" (with cowpox) will be discussed presently.

In 1796 Jenner presented the results of his observations to the Royal Society, but the paper was refused. He then published it in 1798 as a book, "An Inquiry

into the Causes and Effects of the Variolae Vaccinae, a Disease Discovered in Some of the Western Counties of England, Particularly Gloucestershire, and Known by the Name of the Cowpox.\* This book is one of the medical classics, and it should be read in the original by every student of preventive medicine.

In America, the first vaccination occurred on July 8, 1800, when Benjamin Waterhouse of the Harvard Medical School vaccinated his five year old son. After his son and two slaves were successfully vaccinated with cowpox, they were inoculated with smallpox with negative results.

In Boston in 1802 an experiment involving the vaccination and subsequent inoculation of 19 boys took place. This was one of the most crucial experiments in the history of vaccination, and it justified the conclusion of the Board of Health: "Cowpox is a complete security against the smallpox."

Jenner established a fact. A century later Pasteur, impressed with this fact, expanded it into an immunological principle.

### VACCINATION

**Definition.** Vaccination consists in introducing vaccine virus into the skin with the object of inducing cowpox (*vaccinia*) in order to prevent smallpox (*variola*). Vaccine virus contains the active living principle of cowpox. The vaccination or "take" should be regarded as successful only when the course is characteristic. Primary takes occur in persons who are susceptible; modified reactions are indicative of immunity and occur in persons who have previously been vaccinated or who have had smallpox.

For over 80 years vaccination (from *vacca*, a cow) was a specific term limited to the introduction of the virus of cowpox into the skin in order to induce vaccinia and prevent variola. Since the time of Pasteur,\* however, the term has been used in a generic sense to include the introduction of many different substances in many different ways and for many different purposes.

**First Vaccination (Primary Take). COURSE OF THE ERUPTION.** The period of incubation is about three days, when a papule appears upon the skin where the vaccine virus was inserted. The papule develops into a vesicle and this in turn into a pustule, which dries, crusts, and rapidly heals. The papular, vesicular and pustular stages follow each other in orderly succession.

The *papule* is small, round, bright red and hard, but superficial. It appears in about 72 hours. On the fifth day the top of the papule becomes vesicular. The development is rapid so that by the sixth day the papule, which continues to grow, has almost changed to a vesicle. On the seventh day, the vesicle is fully developed and characteristic. It is round, umbilicated, multilocular, with water-clear content—the lymph. The remains of the papule persist as a deep red ring at the periphery of the vesicle and extending out from this there now appears a reddened inflamed area, known as the areola. The stretched epidermis covering the vesicle has a glistening white sheen. This gives the picture of "the pearl upon the rose leaf" which constitutes the true Jennerian vesicle. The development continues so that by the next day (eighth) the vesicle is larger and fuller and the umbilication almost disappears. The

\* Pasteur said of his immunization against anthrax and chicken cholera: "I have given to the word vaccination an extension which I hope science will consecrate as an homage to the name and immense services rendered by Jenner." Valéry Radoy, *Life of Pasteur*, American edition, p. 332.

contents is becoming turbid and the areola is larger. On the ninth day "secondary umbilication" occurs because the vesicle is flattened and less full. By the tenth day the vesicle has turned to a pustule, which develops gradually in size but retains the characteristic round, flat, umbilicated shape. The areola continues to grow. The pustule reaches full development and maximum size on the twelfth day, after which it rapidly dries, the areola fades, and the swelling subsides soon leaving a hard brownish scab or crust which should not be removed. It drops off spontaneously about the twentieth day or later. The scar is at first red and finally turns white, with the pits or foveations so characteristic of the pock mark.

**Modified Reactions and Revaccination.** Although all gradations are found in practice, reactions following vaccination may be classified into three categories according to their characteristics (Leake, 1939), as shown in the accompanying schematic representation (Fig. 1-1).

From Leake, J. P., Pub. Health Rep., Spec. Rept. No. 1137, 1939.

Fig. 1-1. The three types of reaction following vaccination; the height of the curves on different days indicates the diameter of the erythema.

(1) *Primary vaccinia* or the typical vaccination reaction can occur only in an individual who is susceptible to vaccinia and to smallpox. Whatever immunity they may previously have possessed as a result of a vaccination many years before or an attack of smallpox has been lost.

(2) *Vaccinoid* or accelerated reaction. In an individual who has lost part of the protection gained from a previous vaccination or attack of smallpox, the maximum diameter of the erythema is reached in three to seven days. The papule progresses to the formation of a vesicle or vesicles. These may be so minute that they can be seen only with the aid of a magnifying lens; they may dry and disappear rapidly, or they may coalesce and closely simulate the lesion produced in primary vaccines, running a more rapid course to scab formation.

(3) *Immediate reaction* or reaction of immunity. In an individual who is fully protected against smallpox by a previous vaccination or a previous attack of smallpox, the maximum diameter of the erythema is reached and passed in 8 to 72 hours. There is usually enough reaction to constitute a papule, but no vesicle formation.

In making these interpretations regarding the immunity status of an individual who has been vaccinated, due consideration must be given to certain qualifications. The first and most important of these is that immunity can be judged from the type of reaction only if vaccine of full potency \* was used and inserted intradermally by the multiple pressure or scratch method. If the vaccine used has been weakened by time or temperature, the reactions produced will be modified. Vaccinoid reactions may give at early inspection (third day) an appearance similar to that of the immediate reaction. Even if an early reaction is seen, subsequent observations, about the third and ninth days, are necessary to determine whether the reaction was that of immunity, vaccinoid, or vaccinia. Trauma due to the mechanical act of vaccination by the scratch method may cause enough irritation so that redness persists at the time of the 48-hour observation independently of any specific reaction. This is largely avoided if the multiple pressure method of insertion is used. Every vaccination should give a reaction of some type.

McKinnon and Defries (1931) have emphasized that the immediate or early response is not necessarily an indication of immunity. They suggested that it is in reality an indication of allergy to the vaccinia antigens. Craigie and Wishart (1933) studied the human skin sensitivity to washed and killed suspensions of vaccinia elementary bodies. When such a preparation was inoculated intradermally into previously vaccinated individuals an early or immediate reaction usually occurred, whereas in the unvaccinated individual no such response could be elicited. They pointed out that allergy and immunity to vaccine virus are not necessarily related, except in so far as they have common origin in a previously immunizing reaction.

On the other hand, Leake called attention to the fact that the usual reactions of sensitivity as shown by skin tests are rapid, appearing and reaching their maximum within about one-half hour. The fact, however, that reactions otherwise indistinguishable from the immediate reaction to living vaccine may be given by heated vaccine, indicates that at least part of the visible phenomenon which is called the reaction of immunity is given by inactivated antigenic material. If a fully potent vaccine has been used and the insertion has been adequate to produce any reaction whatever after two days, other than the reaction due to trauma, one may conclude that even though this may be due to allergy, or the beginning of a vaccinoid reaction, or the beginning of a primary vaccinia, full immunization is assured by the time the reaction reaches its maximum.

The nature of the modification seen in those who have had smallpox varies with the capacity of the individual to retain immunity. If the interval is less than five

\* A lot of vaccine virus can be regarded as of full potency when, properly applied, it gives 100 per cent of vaccinias (typical primary successes) in every application on at least 100 previously unvaccinated individuals. Leake (1939) suggests that a more practical test is that it should give more than 50 per cent of vaccinoid reactions (accelerated) in unselected persons who have been vaccinated or have had smallpox over 10 to 40 years previously, and on a smaller group, perhaps twenty to fifty persons, will give a good idea of the potency of eruption. Using this criterion trial a batch of vaccine. On rabbits 1:3,000 dilution superficially applied should give a confluent

years, revaccination is apt to give an immediate reaction; between 5 and 20 years there is usually an accelerated reaction; after longer periods of time revaccination may run the course of a primary take. This time correlation applies only in the aggregate, for individual cases vary greatly.

**Methods of Vaccination.** **AGE.** The best time to vaccinate is during the first year of life, but avoiding the summer. There are no contraindications to vaccinating babies shortly after birth, but successful takes are somewhat less frequent than at six months. Vaccination at the age of six months usually proceeds with little or no fever or discomfort. In infants the constitutional reaction from first vaccination is usually much less than in older children and adults, and the risk of complications is practically eliminated. If the infant is to be immunized against diphtheria also, this procedure should be undertaken first and vaccination follow after an interval of several weeks.

Since immunity decreases with the lapse of time revaccination is necessary to afford continued protection. There is some difference of opinion as to just when it is best to vaccinate the second time, but it is generally considered advisable at the time of entering school.

**SITE.** The outer surface on the left arm at the insertion of the deltoid muscle is the most convenient for the operator and the patient. This is the original site selected by Jenner. It is easily kept cool and dry, and is desirable because of the character of the lymphatic drainage. The skin here is easily made taut during the process of insertion by grasping the under side of the arm. Inspection of the course of the local reaction is also facilitated.

Any part of the skin or exposed mucous membrane is susceptible; a take will follow the accidental insertion of the virus into the conjunctiva or the lip.

The leg is sometimes selected to avoid visible disfigurement. With small insertions on the arm, as now practiced, the resulting scar is small, definite and typically pitted, but not disfiguring. The leg is more exposed than the arm to warmth, moisture, and street dust. On account of blood stasis, primary leg vaccinations are often accompanied by purplish discoloration and result in a large, slowly healing ulceration; they usually cause temporary disability. For these reasons this site should be avoided.

The skin at the site of insertion should be surgically clean. Sponge with acetone or alcohol and wait until it evaporates. Do not use denatured alcohol or nonvolatile germicides for they are apt to injure the virus and prevent successful takes. Acetone is an efficient cleanser, is cheap and evaporates rapidly.

Handle the capillary tube containing the vaccine with aseptic precautions and place its contents upon the prepared skin in one small droplet.

**INSERTION.** The objective is to bring the vaccine into contact with the columnar epithelium or basal cells in the lower layers of the epidermis. The injection should be intradermal. Under no circumstances should the vaccine be placed subcutaneously.

*The Multiple Pressure Method* (Leake, 1939). The needle, which should be new, sharp, and sterile, is not thrust into the skin, but is held almost parallel or tangential to it, with the forefinger and middle finger of the right hand above the needle and the thumb below, the needle pointing to the operator's left. The needle should be crosswise of the arm, so that the thumb of the operator is not impeded by hitting the skin. The *side* of the needle point is then pressed firmly into the drop

about 30 times within five seconds (or ten times for primary vaccinations with highly potent vaccine), the needle being lifted clear of the skin each time. This rapid up-and-down motion of lifting the needle and pressing it against the skin should be quite perpendicular to the skin and needle, and not in the direction of the long axis of the needle. The point is not driven into the skin, but at each pressure the elasticity of the skin will pull a fraction of an inch of the epidermis over the point of the needle so that the vaccine is carried into the deeper layers of the epidermis, or just beneath these layers, where multiplication of the virus takes place most easily. The insertion should be confined to an area not more than one-eighth inch (3 mm.) in its greatest diameter. No signs of bleeding should occur and all evidence of the trauma should fade out in a few hours. Immediately after the pressures have been made, the remaining vaccine is gently wiped off the skin with sterile gauze and the sleeve pulled down, the whole operation of pressing and wiping taking less than 10 seconds.

*The Scratch Method.* With a sterile needle make a light scratch one-eighth inch (3 mm.) long, starting in the droplet of vaccine. Only one scratch should be made and it should not be deep enough to draw blood, but a little oozing will do no harm. The excess is allowed to dry in place or is wiped away with sterile gauze. A control scratch is not necessary but is useful for purposes of interpretation and teaching.

*The Intradermal Injection.* For this method a sterile accurately graduated (tuberculin) syringe with a 26 gauge needle is required. About 0.1 ml. of a 1:40 dilution of glycerinated calf vaccine or properly diluted culture vaccine is injected intradermally. The principal objections to the method are the more elaborate materials required, and the greater danger of depositing the vaccine subcutaneously rather than intracutaneously. Subcutaneous applications of smallpox vaccine give reactions which are different from those described as resulting from the intracutaneous, scratch or multiple pressure introduction.

*Scarification.* This consists in rubbing the virus into an abraded surface produced by multiple scratches close together, or by cross hatching. This method is dangerous and should be prohibited.

**AFTER CARE.** Avoid the action of direct sunlight during or immediately after vaccination because of its possible attenuating effect upon the virus deposited in the superficial layers of the skin. Keep the vaccinated area dry, cool and clean. Bathing need not be omitted nor any of the ordinary occupations, but care should be taken not to soften the crust with water or sweat. Unnecessary use of the arm must be guarded against, as this increases the congestion. Vaccine vesicles should be let alone. They should not be opened. Abrasion by clothing or any other form of irritation should be avoided. The vesicles should not be anointed or treated.

No dressing of any kind should be fixed to the vaccination site, but several layers of dry sterile gauze, attached to the inside of the sleeve rather than to the skin, do no special harm provided they are renewed frequently. Shields and pads of any sort are unsafe because they favor softening, breaking down, and secondary infection of the vesicle. If the pustule breaks, or the crust comes off, or the take shows indications of secondary infection, the wound should be treated surgically as an infected wound. The site should be inspected frequently enough to determine whether the take is running a characteristic course.

To summarize, the four most important factors in safe and successful vaccination are the use of a fully potent vaccine, clean technic, restriction of the insertion to a very small and superficial area, and insuring the rapid drying of the vesicle.

**Immunity Conferred by Vaccination.** The specific immunity conferred by vaccination against smallpox appears about the eighth to the eleventh day, that is, about the time at which the areola has reached its height. Since the incubation period of smallpox is frequently 12 days or more, a successful vaccination performed within 24 to 48 hours of the time of exposure to a case can be expected to prevent attack; within two to eight days it may prevent or attenuate the attack; later the vaccination and the smallpox eruption develop concurrently and independently. For protection to be certain the areola of the vaccination should have reached its height before the exposure to smallpox occurs.

The duration of the immunity varies with individuals. Studies based on the reactions following revaccination indicate that the immunity produced by a primary take will, with extremely rare exceptions, protect against vaccinia, and, therefore, against smallpox, for from two to ten years. A few individuals may be protected for a longer time. After revaccination (secondary stimulation) the duration is indefinitely extended, and in some individuals may be lifelong. Nevertheless, it is always relative. Whenever there is danger of exposure to a virulent strain of *variola major* the procedure should be repeated upon all persons who have not been successfully vaccinated or revaccinated within one year.

In the U. S. Army, vaccination at three-year intervals, and within one year prior to departure for overseas areas, has been found to be the most satisfactory routine from an administrative viewpoint. With this provision a few sporadic cases occur each year but all danger of epidemics is obviated. The intervals between vaccinations may safely be lengthened as a person grows older. The way to determine the immunity status of an individual is by observing the character of the reaction after vaccination with vaccine known to be of full potency.

Persons who have had smallpox may, after the lapse of time, exhibit a primary reaction to vaccine virus. This is not strange since second attacks of smallpox may occur in the same individual. On the other hand, there is some evidence to indicate that after vaccination the resistance to smallpox may last longer than does the immunity to revaccination. Likewise, the existence and size of an old vaccination scar bear no direct relation to immunity.

It is a fallacy to state that if repeated attempts to vaccinate an individual fail the subject is immune. A person may be unsuccessfully vaccinated many times before a typical take is obtained. No instance of natural immunity to cowpox has been conclusively demonstrated. Practically everyone is susceptible and the reactions are constant. Even heated (killed) virus will produce an immediate reaction (allergic) in an individual who is immune. The most common cause of failure is impotent virus. Calf lymph deteriorates rapidly unless it is kept extremely cold (see page 21).

The sera of human beings and of monkeys convalescent from vaccination possess neutralizing precipitin and complement-fixing antibodies. Moreover, it has been shown that such sera will agglutinate suspensions of elementary bodies. Interesting and illuminating studies of the nature of these immunity reactions and of the anti-

genic constitution of vaccine virus have been made by Craigie and Wishart, Smadel and Rivers and by others (Smadel, 1948).

**Contraindications.** Patients with generalized eczema and with diabetes should not be subjected to the risk of primary vaccination. On the other hand, if a child is fortunate enough to have had his primary vaccination in infancy, the presence of diabetes or eczema is all the more reason for maintaining immunity by revaccination at intervals of three to five years. Vaccination of an infant in poor nutritional condition or with congenital syphilis should be deferred until the child is in good condition, unless there is an immediate risk of exposure to smallpox. In community protection it is reasonable practice to omit vaccinating the enfeebled, the very sick, and those with infected skin lesions unless they are in danger. Pregnancy is not a contraindication. During the smallpox epidemic in Detroit, 1924, all patients were vaccinated on admission to the Herman Kieffer Hospital, which is the contagious disease hospital operated by the Detroit Department of Health. In all, 3,346 persons were vaccinated, including 773 obstetrical cases and 676 newborn babies, 90 cases of erysipelas, 425 cases of diphtheria, 644 cases of scarlet fever, 368 cases of tuberculosis, and others with measles, mumps, and other diseases. The takes were typical and there were no untoward results. Denny and Hopkins showed that when lepers are vaccinated the reaction is more pronounced than in normal individuals. At the same time, there is a flare-up of the specific lesions of leprosy, which, however, were in no case permanently aggravated; in fact, some showed actual improvement.

**Dangers and Complications.** In the United States the danger from vaccination has been grossly magnified. No figures on the subject are reliable before 1902, when the government passed a law setting up standards of purity and potency of vaccine virus and other biologic products. With proper precautions, the individual risk is now nil.

Vaccination must be looked upon as the production of an acute infectious disease which, although benign, should not be treated as trifling. The danger lies in the fact that we have produced an open wound, which is subject to the complications of any wound. Even a pin prick or a razor scratch may result in death. Before the days of asepsis, bacterial complications of vaccination were a matter of concern. When trouble ensues now, it is in instances where the vaccination was done by scarification or by large insertion, or where the site has not been kept dry, cool, and clean. Shields and other dressings have been the cause of complications; and in some instances infection has been scratched or rubbed into the take. It is now rare to see complications of any sort. In any properly vaccinated case, *the danger is infinitesimal when compared with the benefit conferred.*

Syphilis was formerly a complication in arm-to-arm vaccination, but cannot be transmitted with bovine virus. Tuberculosis and leprosy were formerly thought of as possibilities when human virus was used, but these also are eliminated by the use of bovine virus.

**FOOT AND MOUTH DISEASE.** This has in one instance been demonstrated as a contamination of vaccine virus. It is, however, impossible to convey foot and mouth disease to man through cutaneous inoculation. While no harm has been done to man, the contamination is undesirable and vaccine virus is tested to assure its freedom from this infection.

**AUTOVACCINATION.** Autovaccination is usually due to scratching the virus with the finger into the nose, the mouth, the mucous membranes or any part of the skin.

When carried into the eye it may cause blindness. In vaccine establishments accidental vaccination of the hand is common.

**GENERALIZED VACCINIA.** This is sometimes reported, but may be a mistaken diagnosis. The eruption of vaccinia is nearly always localized about the site of insertion. Satellite vesicles sometimes develop in the immediate neighborhood owing to the spread of the virus into minute nicks in the epithelium. With certain highly specialized strains of virus, generalized vaccinia in rabbits regularly occurs.

**TETANUS.** In view of the tremendous number of individuals vaccinated each year, many without benefit of surgical cleanliness, it is not surprising that tetanus has been reported as a complication, but an extremely rare one. Acland is acquainted with only one instance in more than five million vaccinations in England. Between 1904 and 1914, 41 cases of postvaccinal tetanus were authenticated in the United States. During this same period over 31 million doses of vaccine were distributed by manufacturers of biologic products. Investigations by the officers of the U. S. Public Health Service made since that time have clearly indicated the cause of this complication.

With the exception of an outbreak of postvaccinal tetanus in 1917, traced by McCoy and Bengtson to the use of bone point scarifiers, and of 17 cases traced by Armstrong to the use of infected bunion pads as protective dressings, the sources of the invading organism are unknown. Prolonged search by many workers, using a variety of methods, has failed to demonstrate *B. tetani* in commercial vaccine virus or in other vaccination materials procured from distributors. In 116 cases of tetanus following vaccination investigated by Armstrong (1929a) all developed after primary takes, which had been covered for all or part of their active course by some type of dressing strapped to the vaccination site. The kind of dressings employed were as follows: celluloid shields, 53; gauze, 40; bunion pads, 17; gauze and shield, 5; adhesive bandage, 1. The onset of symptoms of tetanus was found to be usually about 21 days after the vaccination had been performed; or about 10 to 12 days (the usual period of incubation in surgical wounds) after the lesion had reached its maximum reaction. From this and from experimental data, it appeared that the accumulation of broken-down material retained by the dressing at the vaccination site afforded conditions favorable to the growth of tetanus bacilli, accidentally introduced from extraneous sources. Accordingly, Armstrong advised that if a small superficial implantation of the virus be made by the multiple pressure technic, and no protective dressing be fixed to the vaccination site, tetanus would be eliminated as a complication. This advice has been proved correct by the experience of many years in the United States. Not a single case of tetanus has been known to have occurred where these precautions were observed.

**POSTVACCINAL ENCEPHALITIS.** This complication came to notice in 1922 when 11 cases developed in London. Up to 1929, England had reported nearly 100 cases, Holland almost 150 cases, and Germany 34 cases. Sporadic instances have occurred elsewhere. In Germany, there had been one case to approximately every 700,000 vaccinations; in England one to 48,000; and in Holland one to 4,000 (Armstrong, 1929b). In the United States we have a record of 38 probable cases during seven years, 10 of which occurred in 1927 and 13 in 1930.

The anomalous geographic distribution has not been explained. Even in Holland

same localities have an unusual prevalence, others have been spared. It has not been associated with any particular strain of virus.

The period of incubation is constant—10 to 12 days after vaccination. The extremes in the Holland cases were 5 to 20 days. Most of the cases occur between the ages of 6 and 16 years.

The symptoms in postvaccinal encephalitis are headache, vomiting, drowsiness, even coma; rigidity of the neck and Kernig's sign. The spinal fluid is under increased pressure, with a high cell count and sugar content. The case fatality rate is about 33 per cent, death usually occurring about a week after onset. The pathology is similar to that found in demyelinating encephalitis due to other infections, as smallpox, chickenpox, pertussis, measles, and mumps.

The cause of postvaccinal encephalitis is not known. Many students of the disease believe it to be the activation of a latent virus, in the same sense that herpes comes out in pneumonia and common colds. Others consider that it is part of vaccinia, much as nephritis complicates scarlet fever. Vaccine virus has been demonstrated in the spinal fluid of several children with postvaccinal encephalitis, but then the virus occurs there normally as part of a generalization following a take.

The prevention of postvaccinal encephalitis consists in suitable vaccination technique, with a superficial insertion, and no routine dressing. Infancy is the best time to vaccinate so far as this and other complications are concerned. Postvaccinal encephalitis has been observed only in primary vaccination; it has not occurred on revaccination.

**Compulsory Vaccination.** Vaccination affords a high degree of immunity to the individual and a well-nigh perfect protection to the community. To remain unvaccinated is selfish in that by so doing a person steals a certain measure of protection from the community on account of the barrier of vaccinated persons around him.

The laws and regulations (Fowler, 1927) concerning vaccination in the United States show a marked lack of uniformity. Massachusetts,\* Rhode Island, and New Hampshire stand with Hawaii, Puerto Rico, and Guam in requiring the vaccination of public school children. There has been a tendency to relax vaccination laws in a number of states. Utah even went so far as specifically to forbid compulsory vaccination as a prerequisite to school attendance. In England the conscience clause allows many persons to remain unvaccinated.

Decisions in the various courts in the United States have held compulsory vaccination to be legal. A decision of the Supreme Court of the United States (Henning Jacobson v. The Commonwealth of Massachusetts, April 1, 1905) upheld in every respect the statute, the validity of which was questioned under the Constitution:

"The liberty secured by the Constitution of the United States . . . does not impart an absolute right in each person to be, at all times and in all circumstances, wholly freed from restraint. Real liberty for all could not exist under the operation of a principle which recognizes the right of each individual person to use his own, whether in respect to his person or his property, regardless of the injury that may be done to others."

Theoretically, it would be ideal if all persons submitted to vaccination and revaccination voluntarily. But experience has shown that this is impractical, and, wherever tried, has failed. The best results have always been obtained where vac-

\* Massachusetts in 1809 was the first state to enact legislation relative to vaccination.

nation has been required, and this is the only present means by which smallpox may be eliminated.

*Vaccination certificates* should show the name and age; the date of application of the vaccine virus; the nature of the take, whether primary, accelerated or immediate; and the signature of a licensed physician. The data should be based upon observation of the course of the take. Accelerated and immediate reactions are to be interpreted as successful takes.

### VARIOLA INOCULATA

(Variolation) \*

The earlier practice of *inoculation* or *variolation* must be carefully distinguished from that of vaccination. By inoculation we mean the introduction of *smallpox* virus into the skin of man. The disease thus produced is usually mild, but nevertheless is smallpox, and just as contagious as smallpox; moreover, exposure may result in true, virulent smallpox.

Inoculation is a very old custom. It was practiced by the Chinese from time immemorial. The method was introduced into western civilization through Lady Mary Wortley Montagu, who learned of the practice at Constantinople and had her own boy "engrafted" with successful result. In 1717, Lady Montagu wrote her now famous letter to her friend Sarah Chiswell, and inoculation soon became popular in England, 1721, and spread to America and the Continent.† It was introduced into this country by Zabdiel Boylston at Boston. But the disadvantages were early realized and inoculation was soon replaced by vaccination. According to Plehn, inoculation is still practiced in central Africa.

The method of inoculation is similar to that of vaccination. The matter is obtained from the vesicle or pustule of a case of smallpox. This material is then introduced into the skin by means of a puncture, an incision, or through an abraded surface.

Following the inoculation of smallpox virus a local eruption appears on the fourth day at the site of the inoculation. This local eruption resembles vaccinia but develops more rapidly. Constitutional symptoms appear on the evening of the seventh or the morning of the eighth day following the inoculation. These symptoms resemble the onset of true smallpox and are rigor, headache, vomiting, and fever. The local eruption subsides on the appearance of the febrile symptoms but at the same time the general eruption breaks out. The crop is usually discrete, moderate in number, but runs the usual course through papule, vesicle, and pustule formation.

This phase of the subject may be made clearer by considering smallpox as existing in three forms (1) *variola vera* or true smallpox; (2) *variola inoculata* or

\* Variolation with smallpox was also called "suttonian inoculation" to distinguish it from its rival and ultimate successor, jennerian vaccination. *The Inoculator or Suttonian System of Inoculation*, by Daniel Sutton, London, 1796. J. N. Force, Univ. of Calif. Pub. in Pub. Health, 1931, 1: No. 7.

Fowlpox seems to belong to the smallpox family. The virus of fowlpox inoculated into the skin of the leg produces a modified, mild infection which protects. This method is in use on chicken farms.

† The practice of inoculation had been published in England as early as 1714 by Timoni of Constantinople, at Venice in 1715 by Pylarini, and in the same year in London by Kennedy, a surgeon who had been in Turkey. Its adoption and subsequent diffusion, however, were due to Lady Mary Wortley Montagu.

inoculated smallpox; (3) *vaccinia*, cowpox, or modified smallpox. The differences are shown in the following table.

<i>Variola Vera</i>	<i>Variola Inoculata</i>	<i>Vaccinia</i> or Cowpox
True smallpox Occurs only in man	Inoculated smallpox Occurs in man and monkeys	A derivative of smallpox Man, monkeys, cattle, guinea pigs, rabbits, rats, camels, and many other mammals
High mortality—25 per cent in some epidemics A general eruption, often confluent or hemorrhagic	Milder; rarely fatal; about 1 in 500 A local and a general eruption, fewer pustules (rarely over 200); seldom confluent or hemorrhagic	Benign; never fatal Always local and confined to the site of the vaccination
Highly contagious	<i>Equally highly contagious</i>	Not contagious — contracted only by mechanical transfer of vaccine virus
Period of incubation twelve days	Eight days' incubation	Three days' incubation

Emphasis must be placed on the fact that *variola inoculata*, while usually a mild disease, is just as communicable as true smallpox, and those who contract the disease in this way get true smallpox, sometimes in serious or fatal form. *Inoculation, therefore, protects the individual but endangers the community.*

Inoculation has fallen into disuse only because we have vaccination. There are conceivable emergencies in which the practice would be justified, for example, on board ship or on an island or in an out of the way place, in the absence of vaccine virus. Under such circumstances it would be essential to inoculate everybody at the same time.

The inoculation of smallpox will always remain for the student of hygiene one of the most interesting episodes in the development of preventive medicine. It illustrates in the clearest manner some of the fundamental phenomena of infection, susceptibility, and immunity. It was animal experimentation on a huge scale, the like of which we shall never see repeated on man as the subject. It is now a matter of regret that for the sake of science better advantage was not taken of the data.

### VACCINE

*Vaccinia*, or cowpox, is an acute specific disease, which runs practically the same clinical course in all susceptible species. The virus is widely distributed in the body. The eruption is local and confined to the site of the vaccinated area; the constitutional symptoms are mild. *Vaccinia* or cowpox is a benign disease; when uncomplicated, it has never been known to cause death or leave any unpleasant sequelae.

**Is Cowpox Modified Smallpox?** The unity or duality of these two diseases has been the subject of much contention. Jenner considered cowpox to be modified smallpox. The successful experiments in Germany, England, and this country, in which smallpox has actually been modified by passing variolous matter through calves, has demonstrated that we are dealing with two forms of one disease. When smallpox is thus converted into cowpox, it remains fixed as such and never reverts

to smallpox. Twenty-nine separate records of successful modification of smallpox virus into cowpox are found in the literature; also a number of negative attempts. Some of the strains obtained in this way have been used to vaccinate with typical takes and adequate protection.

Immunity to the acute communicable infections as a general rule is specific; in fact, it is a general principle in immunology that acquired immunity is usually exquisitely specific. This lends countenance to the assumption that cowpox is a derivative of smallpox.

**Spontaneous or Casual Cowpox.** The disease is said to occur "spontaneously" when its origin cannot be traced. It seems likely that so-called casual cowpox had its origin from smallpox through accidental inoculation in milking cows by persons having or recovering from smallpox. Once started, the propagation of the modified virus from cow to cow would be comparatively simple. It is highly significant that casual cowpox was much more common when smallpox was much more prevalent. In 1866 an instance of casual cowpox was discovered in Beaugency, France, and this virus, known as the Beaugency strain, has since been widely used.

**Strains.** Some strains of virus are more active than others. The original dermal strain has been adapted to other epidermal tissues, so that we have neurotropic and testicular strains.

*Vaccine virus* is the living specific principle in the matter obtained from the skin eruption of animals having "vaccinia" or "cowpox." Vaccine virus ordinarily is obtained from calves, but may also be obtained from older cattle, from man, rabbits, buffalo, caribou, camels, and other mammals.

*Seed virus* may be obtained (1) from casual cowpox, (2) from smallpox modified by passage through calves and (3) by retrovaccination. Each produces typical takes and adequate protection.

*Human virus* is no longer used on account of the risk of transmitting syphilis and perhaps other diseases peculiar to man. Another disadvantage is that it is not practicable to obtain the great quantities needed, especially at the time of an epidemic demand.

*Bovine virus* has been used since the time of Jenner, but especially since 1891 when Copeman showed the possibility of purifying it. Bovine virus has the great advantage of being readily obtainable in any amount and when desired. It may be purified with glycerin and phenol, and it further totally eliminates the danger of conveying syphilis and other diseases peculiar to man.

**Retrovaccination.** When vaccine virus is passed from calf to calf through a long series of transfers, it has a tendency to lose virulence and to give weak takes or failures. Serial propagation from animal to animal of the same species also tends to establish strains of associated skin bacteria with the virus. These bacteria may be repressed and even eliminated and the virulence of the vaccine virus restored simply by changing species from time to time. This is known as retrovaccination and is usually carried on by transferring the virus from calf to rabbit to calf; or, the virus may be passed from man through rabbit, monkey, or other susceptible animal back to the calf.

## PRODUCTION OF VACCINE VIRUS

**Propagation.** In the propagation of vaccine virus calves are preferred, because they are more manageable, the skin is more tender, and the eruption is, therefore, more abundant and typical. With young animals a milk diet may be used, which simplifies the problem of dust contamination from dry feed. If hay or fodder is used, it should first be autoclaved. Either heifers or bull calves are suitable, although the former are preferred.

The animals are held in quarantine for seven days under observation, to determine the absence of infections such as tuberculosis, glanders, foot and mouth disease, tetanus, fever, diarrhea or skin eruptions of any kind.

Before vaccinating, the calf is carefully cleaned and the site of the vaccination is shaved and prepared surgically, but without the use of strong germicidal solutions, for the reason that they may destroy the activity of the vaccine virus. Cleanliness and asepsis are the watchwords. The area selected is usually the abdominal wall between the tip of the sternum and the groin, sometimes including the inner side of the thigh. The usual method is to make long, superficial incisions in the skin about one centimeter apart, and the seed virus is gently rubbed into these incisions. The calves must then be kept rigidly isolated in a special room, moderately lighted, free from dust, and screened to keep out insects. The temperature of the animal is taken several times daily and the eruption at each stage of the disease is closely watched and recorded.

The virus is usually taken from the animal about the fifth day. It is an advantage to do so this early in order to avoid contaminating infections which may occur when the vesicles mature. Jenner's golden rule was to take the virus before the areola appeared; that is, before the seventh day. Virus taken after the eighth day is apt to produce unduly inflamed or abortive vesicles, called spurious takes by the early vaccinators.

The vaccination site is scrupulously cleaned by repeated washing and scrubbing and the pulp is then removed with a sharp spoon curet. Only typical and entirely characteristic vesicles are removed. Before the virus is taken, the animal is chloroformed or killed to avoid pain, and an autopsy is done after the virus is harvested. If the autopsy shows any lesions indicating infections other than vaccinia, the virus is discarded.

**Purifying or Ripening of Vaccine Virus.** Vaccine virus obtained from the skin always contains bacteria. The initial contamination may be lessened by care in propagation and harvesting of the virus. After collection, the virus may be treated to reduce greatly the number of bacteria which it contains. In the United States, vaccine virus is required to have fewer than 50 bacteria per dose and these must be nonpathogenic as determined by tests.

In 1891, Monckton Copeman made the important discovery of the selective action of glycerin for purifying vaccine virus.\* The glycerin acts as a differential germicide; that is, it is comparatively harmless to the virus but destroys the frail, nonspore-bearing bacteria. In time the virus itself succumbs.

\* Glycerin also serves as a preservative for other filtrable viruses, as foot and mouth disease, infantile paralysis, rabies, etc.

In practice, 2 to 4 parts of 50 per cent glycerin are added to 1 part of the pulp by weight. The amount of glycerin added depends upon the consistency and character of the pulp. The pulp should be thoroughly broken up and a uniform suspension obtained. The time required for the virus to lose most of its bactericidal effect depends upon the temperature. Most of the nonspore-bearing bacteria perish in 30 days at 15° to 20° C. Approximately the same effect may be obtained at 37° C in a few hours. At low temperatures the glycerin has practically no bactericidal effect. The process must always be controlled bacteriologically.

Phenol is commonly added to the pulp in 0.5 per cent concentration, to reinforce the bactericidal action of the glycerin. Both phenol and glycerin are selective germicides.

Because these agents exert a gradual destructive effect on the virus itself, old glycerinated virus is apt to be inert. Manufacturers in the United States date their products as potent for not more than three months "if kept below 5° C."

**Fresh Virus and Dried Virus.** Vaccine matter when dried remains potent for a long time, especially when dried, frozen and protected from oxygen and light. Formerly, physicians preserved the dried crust from a typical take. The old-fashioned dry points were prepared by drying vaccine lymph on splinters of ivory, and later on bone or glass. Dried virus still has a limited application in tropical countries because of its greater resistance to destruction by heat. Glycerinated virus should, however, be used wherever practicable.

**Government Control of Vaccine Virus.** By the law of July 1, 1902, vaccine virus sold in interstate traffic in the United States must come from a licensed manufacturer. These licenses are granted for one year by the U. S. Public Health Service after a careful inspection of the plant, personnel, and product, and are reissued only after reinspection. Each lot of vaccine virus must be examined carefully by modern bacteriological methods to determine the number of bacteria; tests including animal inoculations as well as cultural methods must be made to rule out pathogenic microorganisms. The government does not guarantee the purity and potency of each package of vaccine virus, but through its inspections and frequent examinations of the virus on the market every confidence may be had in the vaccine virus distributed by licensed manufacturers in this country.

**Care of Vaccine Virus.** Vaccine virus should always be kept ice cold until used. The warmth of the doctor's pocket, the office desk or the druggist's shelf may be enough to impair seriously its potency in a few hours. The heat of the railroad car or post office may soon render it impotent. This explains the difficulty sometimes encountered in obtaining potent virus during the summer months. Ice-box storage may not be enough. The packages of virus should be kept in small glass or metal containers in actual contact with ice. In an electric refrigerator packages of vaccine should be kept in an ice-making compartment. The ideal is that vaccine shall not be more than 30 minutes out of cold storage (below freezing) and that during the interval from removal up to the moment of use it shall be kept in a bowl of ice. Smallpox vaccine which has been out of cold storage so that it gives only about 80 or 90 per cent of successful vaccinations on previously unvaccinated individuals is not satisfactory and may be dangerously weak in the presence of severe smallpox.

Freezing does not injure vaccine virus; in fact, virus kept below freezing may

preserve its potency for years. Recent virus keeps better and gives more vigorous takes than old material. It is always advisable to keep a record of the name of the manufacturer and the lot number and expiration date found on the package. The handling of the container and capillary tubes should be governed by the principles of rigid asepsis.

**Egg Culture Virus.** Following the pioneer work of Goodpasture and his co-workers in 1935, a number of workers have shown that vaccinia virus will proliferate when inoculated onto the chorio-allantois of the fertile hen's egg. The possibility of using this method of production for vaccine was immediately realized. Certain advantages were obvious. Such a vaccine can be obtained completely free from bacterial contamination; it is relatively simple to prepare; it is cheap and obviates the necessity of using calves; if at any time there is an extraordinary demand for vaccine, this can be quickly met by inoculating a sufficient number of eggs. Preliminary studies by Goodpasture and his collaborators, and others, of the use of this material on animals and human beings indicate that its antigenic powers are similar to those of calf virus. The proportion of successful takes is comparable and the character of the reaction somewhat milder. The durability of the immunity and the protection afforded against natural exposure to smallpox, of virulent and mild types, has not yet been established by human trial.

There is some question as to whether a passage strain of vaccine virus cultivated on egg membrane remains stable in its properties, that is, whether its virulence may not suddenly increase or decrease. Until technical problems have been satisfactorily solved, the method remains in the experimental stage.

**Tissue Culture Virus.** Rivers and others (1939), and a number of other investigators have explored the use of preparations of tissue culture virus for human vaccination. It has advantages of the same order as those mentioned for egg culture virus; it also presents problems of the same nature. Preliminary trials are encouraging, but the method must still be regarded as experimental. Since the material is sterile it can be diluted and injected intradermally in precise quantities with a tuberculin syringe. Primary takes are milder than those with calf vaccine, and it is possible that the method may find a particular field of usefulness in giving a primary antigenic stimulus to infants with the least amount of disturbance.

## CHICKENPOX

(*Varicella*)

Although characteristic features of chickenpox were described as early as 1767 by Heberden, it is not surprising that it was confused with smallpox until the nineteenth century. At times even today these two diseases are differentiated with considerable difficulty.

The usual incubation period of chickenpox is 13 to 17 days, the maximum for isolation purposes being 21 days. The prodromal period is short. The onset is sudden with some elevation of the temperature and mild constitutional symptoms. Within 24 to 48 hours the eruption makes its appearance. In the milder cases it may be the first symptom noted. In contrast with the smallpox eruption which comes out as a single crop, in chickenpox there is a succession of crops, new lesions continuing to appear for three to four days even upon the same part of the body. For this reason they may be seen in all stages of evolution at the same time. Some lesions do not go beyond the papular stage, but most of them become vesicular. In general, the vesicle is more superficial. The surrounding areola and indurated base is smaller and less marked than in smallpox. While in chickenpox the vesicles tend to be more abundant on the covered portions of the body, in smallpox the reverse is true. For this reason indurated papules are found less frequently in the palms of the hands and on the soles of the feet than in the latter. The vesicles dry; crusts and scabs are

formed which fall off in 5 to 20 days depending upon the depth to which the skin has been involved.

As with *variola minor* the case fatality rate is extremely low. Probably no one ever dies of chickenpox per se. Complications are infrequent, but in debilitated persons, adults, and infants may cause death. The case fatality rate for all ages rarely exceeds 0.4 per cent. In severe cases with recovery a few scars and pockmarks may remain.

While in typical cases chickenpox and smallpox can be differentiated on the basis of clinical evidence alone, instances occur in which this is insufficient. This may be the cause of considerable embarrassment to the practicing physician and the health officer, and is a matter of considerable importance to the community. From the point of view of civic safety, where there is reasonable clinical doubt, the suspicion of smallpox should be entertained until this possibility can be dismissed. Further evidence is sought along three lines—the previous history of the patient, the source of the infection, laboratory procedures and, upon occasion, the result of a vaccination done after convalescence.

The history of the patient should receive consideration with reference to previous attack from smallpox or chickenpox or both, bearing in mind the possibility of a second attack of either. Of similar importance is the vaccination history; the existence of a vaccination scar must be interpreted with reference to time. Though smallpox is more frequent in the unvaccinated, neither the vaccination history nor the presence of scars should be given much diagnostic weight.

Inquiry into the source of the infection will usually reveal the clinical characteristics of the case or cases from whom the patient was infected. Where doubt remains during convalescence, it may be removed by the manifestations of disease in the exposed contacts. A successful take, primary reaction, obtained with vaccination after recovery is reasonable proof that the suspected illness was not smallpox; on the other hand, a vaccinoid or immediate reaction does not prove that it was, even though the history of previous attack and of previous vaccination be negative. Occasionally, diagnostic laboratory tests are resorted to in order to establish whether or not the virus is that of smallpox (see page 5).

**Chickenpox Virus.** The causative agent of chickenpox is a virus similar to that which causes smallpox but is immunologically distinct. Characteristic elementary and inclusion bodies have been described. It is closely related to the virus which causes herpes zoster (shingles), but evidence that they are identical is not conclusive.

Experimental animals so far tested are refractory with the possible exception of young vervets and green monkeys (Rivers, 1926). Little is known as to its resistance to external conditions and to physical and chemical agents. It seems reasonable to suppose that it is not essentially different from vaccinia in these respects.

**Host Relationship.** So far as is known man is universally susceptible to this infection. It is thought that the virus enters through the respiratory tract and is distributed by way of the blood stream to the cutaneous tissues and mucous membranes. Here it proliferates and can be demonstrated in fluid from the vesicles.

Epidemiological evidence indicates that the patient ill with this disease is infectious for contacts from about 24 hours before until about 6 days after the appearance

of the eruption. The crusts and scabs persist for a much longer period but do not appear to be the source of contact infections (Gordon and Meader, 1929).

The virus makes effective exit from the human body principally, if not solely, in secretions from the upper respiratory tract, perhaps as a result of the breakdown of mucous membrane lesions which occur early in the course of the disease. Transmission to a new host is effected by air-borne droplets and droplet nuclei, and perhaps less frequently by contaminated articles. It is one of the most readily communicable of diseases.

In the United States about 70 per cent of persons who have reached adolescence give a history of having had a clinical attack. Mild attacks with very little if any constitutional disturbance and a few lesions scattered over the body commonly escape recognition. The existence of true subclinical infections or of healthy carriers has not been proved. A single attack confers a durable immunity.

Man is the reservoir host of the virus and it maintains itself in human populations by case-to-contact transfer. In all large communities it is constantly endemic, although the incidence rises during the winter and spring months. The smaller and more isolated communities may escape for periods of time. When the infection is introduced by an imported case, the rapidity and extent of spread is determined largely by the immunity status of the exposed population.

**Prevention.** Recognized cases should be isolated. Exclusion from school is generally required. Restrictions upon the patient can be terminated safely at the end of seven days, even though a few crusts and scabs may still be present on the skin. Public opinion may demand isolation until all crusts and scabs have disappeared. Susceptible contacts may be permitted to continue normal activities until 12 days from the earliest exposure date; during the succeeding week they should be carefully observed and excluded from school upon appearance of symptoms.

Because of the high degree of communicability, the frequent occurrence of mild missed cases, and because the patient is infectious for 24 to 48 hours before diagnosis is established, community spread can be retarded or reduced by isolation procedures, but only occasionally prevented.

Vaccination with chickenpox virus has been proposed, but for many reasons it is not practical at present.

#### MEASLES

(*Morbilli, Rubeola*)

Morbilli is the diminutive of morbus, little disease, in contrast with smallpox. Rubeola is derived from the Arabic meaning red spots. Rhazes of Bagdad, about 900 A.D., clinically differentiated between measles and smallpox. The credit for separating measles from scarlet fever is given to Sydenham whose works were published around 1675, but he did not distinguish between measles and smallpox. The latter differentiation was reasserted in English medicine by Withering in 1792,

Recognition of German measles (Rubella) as a distinct entity dates from the early nineteenth century.

**Clinical Manifestations.** Measles is the most widely distributed and most commonly recognized of all of the eruptive fevers to which man is subject. It is also the most constant in its primary clinical manifestations. Mild abortive cases which cannot be clinically identified are relatively rare. Inapparent infections and convalescent carriers are not known to occur. The incubation period is commonly 10 days from exposure to appearance of recognizable symptoms, about 12 to 14 days from exposure to appearance of rash (Sartwell, 1950).

The onset of the disease is marked by the appearance of fever and malaise followed promptly by catarrhal symptoms which increase up to the development of the eruption. The characteristic symptoms of the pre-eruptive stage are those of severe coryza—suffusion of the eyes, increased lacrimation, photophobia, sneezing, discharge from the nose—and cough. The first manifestations of the eruption usually become evident from two to six days after the onset. Before the cutaneous eruption the spots described by Koplik in 1896 appear upon the buccal and labial mucosa.\* The cutaneous erythematous, maculopapular measles eruption begins to effloresce and extends rapidly to the entire body. In an uncomplicated case the temperature returns to normal in three to five days. Within a day or two after the fever has ceased the rash has disappeared except for a pale residual pigmentation which may last for a few days longer. A fine branny desquamation follows.

Measles per se is seldom fatal, but the morbid process which it initiates upon the mucous membranes of the upper respiratory tract lowers resistance to invasion by potentially pathogenic micro-organisms already present or which are acquired during the course of the disease. Most common is an ascending infection involving the sinuses or the middle ear. The greatest danger arises from pulmonary complications which are responsible for nearly all fatalities.

If roentgenograms are made routinely, pneumonic infiltrations are found in about one fourth of the cases in the pre-eruptive stage and in approximately one half as the eruption subsides. The mediastinal lymph nodes are often considerably enlarged, even when pneumonia is absent; this enlargement may persist into convalescence. The early appearance of these lesions supports the view that they are initiated by the virus itself, a conception which also receives support from the studies of measles pathology. The initial process is a peribronchial pneumonitis, but it is rapidly obscured by the invasion of pyogenic micro-organisms, causing broncho-pneumonia. A small proportion of cases go on to the development of empyema, and chronic pneumonia with bronchiectasis.

**Frequency of Complications and Death.** As is seen in the accompanying tabulation, the death rate from measles, as from other common communicable diseases of childhood, has decreased remarkably during the past half century in the Death Registration Area of the United States. Most deaths occurred in children under

\* According to Koplik, they are described as "small, irregular spots of a bright red color. In the center of each red spot is seen a minute bluish white speck. There may at first be only two or three or six such, rose-red spots, with a bluish white speck in the center. The combination of a bluish-white speck with a rose red background on the buccal and labial mucous membrane is absolutely pathognomonic of the invasion of measles. Sometimes the bluish white speck is so small and delicately colored that only in a very direct and strong daylight is it possible to bring out the above effect, but the combination is always present."

Table 1-2. Death rates per 100,000 estimated midyear population for common infectious diseases of childhood

Cause of Death	Death Registration Area, United States						
	1910	1920	1930	1940	1945	1947	1950
Measles	12.3	8.8	3.2	0.5	0.2	0.3	0.3
Scarlet fever	11.6	4.6	1.9	0.5	0.2	0.1	0.0

Figures from U.S. Mortality Tables.

three years of age. Under ordinary conditions of prevalence in the civilian population, case fatality rate in children under one year of age is less than eight, during the second year less than four, during the third year less than two, and throughout the rest of childhood and adult life a fraction of 1 per cent. With the introduction and effective use of antibiotics for the treatment of complications, where good medical service is available, the risk of death has been reduced to a very low level indeed in all except very young infants.

Historically, there are on record widespread epidemics of measles in "virgin" populations accompanied by high mortality rates. These have occurred particularly among uncivilized people, living under very primitive conditions, in the absence of all rational treatment of the sick (Hirsh, 1883). A classical example is the epidemic of measles in the Fiji Islands in 1875 as reported by Squire. These islands had been free from the disease for many years. The native Chief, Thacombau, returning with his retinue from a visit to Sydney, Australia, introduced the infection. The disease spread rapidly throughout the islands. During the succeeding four months the estimated deaths were 20,000, or one fourth to one fifth of the native population. "Thousands were carried off for want of nourishment and care as well as by dysentery and congestion of the lungs; the worst dangers from overcrowding were incurred in the small houses and the worst danger from cold by the sufferers rushing into the water where they would continue immersed."

At times, measles has been a disastrous disease among military populations. An illustration is the U. S. Army experience in 1917-1918. In some of the camps which were filled with recruits from rural sections of the south there were sharp outbreaks of measles. Cases were hospitalized and there was a high incidence of secondary pneumonia. Among the 4,000,000 troops there were 96,817 admissions for measles; 2,367, or 2.4 per cent, of these terminated fatally. Dunham estimates that the case fatality rate for post-measles pneumonia was 35 per cent. On this basis there were some 6,700 cases which had this complication. In some camps the proportion of measles cases which developed secondary pneumonia was much higher than in others. Studies made by Army Commissions indicated that hemolytic streptococci and pneumococci were the most common secondary invaders (Opie and others, 1921). In the 1951 epidemic in South Greenland there was a morbidity rate of the order of 99.8 per cent, with 4,320 cases and 77 deaths.

In civil populations, Godfrey (1928) has called attention to the large proportion of the total measles deaths which occur in institutions caring for young children and the high case fatality rates which may prevail. In one group of these institutions, in which there were two epidemics during 1916 and 1918, the case fatality rate for all children was 24 per cent, for children under one year it was 45 per cent. These high rates were attributed to undernourishment, overcrowding and inadequate care during the epidemics. When practical methods were introduced to give better medical care, the case fatality rate for all ages was reduced to less than 2 per cent. From this experience it would seem that the case fatality rate is very largely determined by the character and adequacy of medical care.

Panum's *Classic Studies on Epidemic in the Faroe Islands*. Much that we know about measles was contributed in the admirable report of Panum (1847) who was sent to the Faroe Islands in 1846 as a member of a medical commission to study an outbreak of measles. Measles had disappeared from the Faroe Islands in 1781, so that they were free of the disease for a period of 65 years when the epidemic of 1846 occurred. It was brought into the Islands by a cabinet maker, who left Copenhagen March 20 and reached Thorshaven on March 28 in good health. A few days before leaving Copenhagen he had come in contact with a case of measles, and on the fourteenth day thereafter, some days after reaching Thorshaven, he developed the disease.

Panum demonstrated that the period of incubation of the disease is usually 13 or 14 days; that all ages are susceptible; that one attack produces a definite immunity; that the disease is most readily transmissible at the time of the development of the eruption, but that it may be transmitted during the prodromal period and before the appearance of the rash, but in no instance did he find that it was transmitted during the period of desquamation.

Out of 7,864 inhabitants of the Faroe Islands, about 6,100 had measles. There were 170 deaths—a case fatality rate of 2.8 per cent for all ages, but 28.6 per cent for infants under one year of age.

**Experimental Measles.** In the literature of the eighteenth and nineteenth centuries, beginning with the treatise of Home in 1759, there are to be found a number of accounts of human inoculations with blood and other materials taken from measles patients. Suggested by the procedures of inoculation or variolation as a prophylactic measure against smallpox, this so-called *morbillisation* was attempted with the object of inducing a mild disease which would lead to a permanent immunization of the subject. Hektoen (1905) critically reviewed these old reports. He concluded that, although it is exceedingly probable that measles was often produced as a result of inoculation, the possibility of intercurrent natural infection through contact a posteriori could be absolutely excluded.

Monkeys belonging to the several species of the genus *Macaca* have been shown to be susceptible (Shaffer and others, 1941), but are more resistant than human beings. When successfully inoculated they present a clinical symptomatology somewhat similar to that of a mild, abortive case in man. The virus can be recovered from the buccal mucosa of infected monkeys killed two to six days from onset, and from the blood during the first five days of the illness. Similarly, it is present in the blood and the nasal and buccal secretions of human patients 24 and often 48 hours before the appearance of the eruption, as has been shown by inoculation experi-

ments and by instances of accidental infection from transfusion. It persists in the blood and secretions for at least 24 hours after the appearance of the eruption, but cannot be recovered after the temperature curve has begun to subside. The desquamated skin is not infectious.

Many attempts have been made in recent years to grow the virus of measles in tissue culture. Some were unquestionably successful. Particularly notable is the demonstration of Rake and Shaffer (1940) that measles virus could be grown on the chorio-allantoic membrane of the developing chick embryo in successive passages. It was subsequently found that (Shaffer and others, 1941) virus from the early egg passages is capable of producing mild measles in the monkey and a slightly modified disease in man. Some of the monkeys developing typical measles from passage virus were subsequently resistant to challenge with active virus from human sources. Furthermore, it was demonstrated that passage virus could produce mild measles with typical Koplik spots in small groups of susceptible children. Later passages of the egg culture virus resulted in a greatly modified disease with slight symptoms or signs or nothing at all.

**Experimental Vaccination of Children with Measles Virus.** An extensive study of the usefulness of the vaccine produced by the growth of measles virus in the chorio-allantoic membrane of fertile hens' eggs was undertaken by Maris and others (1949). Their conclusions were that the chorio-allantoic membrane vaccine produced mild symptoms of measles in a large number but not in the majority of children vaccinated. Whatever protection was afforded by vaccination procedure was minimal in degree. The reasons for the failure of the vaccine to afford better protection are not evident.

**Transmission.** The virus is an obligate parasite of the upper respiratory tract of man. No other animal species is known to be naturally infected. Transmission to a susceptible person is effected directly by droplets or droplet nuclei expelled during talking, coughing, or sneezing. The virus may also be transmitted indirectly by articles freshly soiled with buccal or nasal discharges. The contagion can be indirectly conveyed by droplet nuclei in air currents for short distances and time periods in enclosed spaces. The virus dies within a few hours outside the body. Accordingly, transmission by infected droplet dust particles and contaminated articles becomes a relatively unimportant medium.

**Prevalence.** Measles is propagated in the human race by chain transmission from cases to susceptibles. Under modern conditions of living and transportation the disease is never long absent from any community. It is continuously propagated throughout the year and from year to year in all large cities.

An infant enjoys immunity from infection during the first few months of its life provided the mother has had the disease. Thus, in any community a susceptible population is constantly being recruited by maturing infants and by new arrivals who have not had the disease. Exposure to infection is inevitable. The rate at which measles is acquired in urban communities is indicated by the accompanying figure (Fig. 1-2). Approximately 95 per cent of the children at the age of 15 have previously had measles. Depending upon circumstances in a rural or isolated area exposure may be delayed and a greater proportion of individuals remain susceptible into adult life. A single attack confers a high and durable immunity. Although second attacks may occur they are extremely rare. Thus, Panum observed: "Of the

many aged people still living on the Faroes who had measles in 1781, 65 years previously, not one, as far as I could find out by careful inquiry, was attacked the second time. I myself saw 98 such old people who were exempt because they had had the disease in their youth. This was the more noteworthy in that a high age by no means lessened the susceptibility to measles, since, so far as I know, all the old

Fig. 1-2. Four observations of measles history by age; also, calculated rates for Baltimore.

people who had not gone through with measles in earlier life were attacked when they were exposed to infection."

This process of conversion of susceptibles into cases and cases into immunes goes on in all human communities intermittently or continuously. There are periods when transmission is going on at a rapid rate (epidemic prevalence) and periods when the disease is being propagated at a low level, smouldering in the population (endemic prevalence). In the smaller communities there are periods when the disease is absent. Over a half century ago it was realized that the principal factor which determined epidemic spread was the accumulation of susceptibles in the population (Hamer, 1906). When the proportion of susceptible persons reaches a level which is critical in relation to climatic and other external conditions in a community, the disease tends to spread widely. As cases are converted into immunes, the proportion of susceptibles falls. The accumulation of immunes acts as a damper upon further spread. The rise and fall of incidence is thus explained as due very largely to the balance between the proportion of susceptibles, cases and immunes in a population. It is further modified by climatic and other environmental conditions. The colder months of the year are more favorable to transmission than are the warmer months. Consequently, measles exhibits a more or less constant seasonal pattern. In all large population groups the prevalence reaches a maximum during the late winter or early spring months and minimum during late summer months. In addition to the regular seasonal increase and decrease there is an interannual

variation which is manifested by peaks or epidemics recurring at intervals of two, three or more years.

**Immune Globulin.** After an attack of measles the blood is rich in immune bodies able to neutralize the virus of measles. This property of the blood gradually weakens with the years but retains its efficacy for life. Convalescent serum obtained between the tenth and thirtieth days is most effective—from three to five times as protective as adult serum obtained many years after an attack of the disease. There is no accurate quantitative method of measuring the potency—the efficacy is determined by clinical results.

Five ml. of convalescent serum for a child and 10 ml. for an adult will usually protect against measles if given before the middle of the period of incubation, namely, the fifth day after exposure. The protection is passive and transient and cannot be depended on for more than about three weeks. If adult serum is used, 15 to 20 ml. will protect. Injections are given intramuscularly.

If given after the middle of the incubation period (between the fifth and eighth days) the serum will not prevent but is likely to modify the disease. This modification consists in a prolongation of the period of incubation (17 to 18 days) and amelioration of the severity of the attack. There is usually fever and some catarrhal symptoms, but the Koplik spots or the rash may be absent. Large doses of serum are required during the catarrhal stage to lighten the symptoms. After the rash appears, the serum has no apparent effect.

There is great advantage in giving the serum during the middle third of the period of incubation so as to produce a mild attack, for the reason that this is followed by a lasting active immunity. Whereas, if the serum be given during the first part of the incubation period and the disease prevented, the immunity is passive and transient. The only exception to this rule is in feeble or tuberculous children who should be spared measles, however mild.

Fig. 1-3. Effect of measles convalescent serum with reference to time of administration; also, typical temperature curve of the disease.

Figure 1-3 shows graphically the effects to be expected with convalescent serum. The results are sometimes disappointing or different because of varying antibody content and time after exposure.

McKhann and his associates (1935) showed that serum contained in human placentas could be purified and concentrated to give an antibody concentrate (immune globulin) or placental extract which was as potent as the average convalescent serum. Apparently, because of the nature of the raw material and certain processing difficulties inherent in the method, local and systemic reactions have been noted following the use of placental extract and its usefulness has been correspondingly limited, moreover, it entails the risk of inciting serum hepatitis.

The development of a large scale blood procurement program during World War II and the correspondingly unprecedented quantities of human plasma which became available made possible a new approach to the provision of measles antibodies from normal adult human blood. A considerable proportion of the blood collected for military purposes was fractionated by Cohn and his associates (1944) to produce gamma globulin. It has been shown that gamma globulin (immune globulin human) contains measles antibody in a concentration about 25 times that found in the original plasma from which it was made (Enders, 1944).

Several studies have demonstrated the efficacy of gamma globulin or immune serum globulin in the control of measles. It is known to have a consistently higher and a more uniform potency and greater freedom from reactions than any other generally available form of measles antibody. By proper adjustment of the dose it is possible in most cases to select either modification or protection as the objective (Janeway, 1944). Modified measles is desirable for healthy children over three years of age, except in those unusual circumstances which justify complete protection. Modification can usually be obtained by the injection of .02 to .025 ml. of gamma globulin per pound of body weight, preferably within four or five days of known exposure to measles. If modification is obtained the incubation period is frequently prolonged to as much as 17 to 21 days, catarrhal symptoms are usually slight, temperature lower, Koplik spots may be absent, and the rash may be mild and transient. Complications are practically never seen. Modified measles is probably just as infectious as the unmodified form. Therefore, if a quarantine is to be imposed, it should be extended to three weeks after exposure. If the course of the disease is too greatly modified it is questionable whether the immunity conferred is sufficient to afford durable protection.

Complete protection of an exposed susceptible from measles may be obtained for perhaps three to four weeks by injection within six days after known exposure of .075 to 0.1 ml. of gamma globulin per pound of body weight. Such protection is justifiable in children under three but not in infants under four months, in children who are debilitated or otherwise ill, particularly with tuberculosis or rheumatic fever, in institutional groups, in pregnant women and in a few other special situations. The immediate apparent advantages of complete protection should always be weighed against the temporary nature of the protection obtained, which necessitates repetition of the dose at intervals of three to four weeks if exposure to measles continues to occur, against the fact that any blood product is now, and always will be, difficult to supply in quantities sufficient for those who really need it.

**Prevention.** There is no satisfactory evidence that in large communities the spread of measles can be materially reduced by isolation of patients and restrictions placed upon susceptible contacts. The principal reason is that it is contagious in the pre-eruptive, ambulatory stage before diagnosis is made. Moreover, since it is generally regarded as an unimportant disease of childhood, many cases are not brought to the attention of physicians. Exposure for every individual is inevitable. The only permanent protection is by the acquisition of immunity by having measles. In view of these considerations, preventive measures are directed principally toward reducing the frequency of complications and death.

The chief objectives are (1) to provide adequate medical care for every case of measles, (2) to protect so far as practicable the exposure of children under three years of age. Cases should have bedside care and, if possible, separate room isolation at home. Hospitalization is undesirable unless isolation facilities are adequate. Isolation not only tends to reduce spread to the remaining susceptible contacts but, equally important, serves to protect the patient from exposure to dangerous secondary infection during a period of lowered resistance of respiratory mucous membranes. Protective isolation of measles should be continued until convalescence is established. Services of a physician should be readily available to institute therapy with antibiotics in the event of complications. Ordinarily, in large communities, quarantine of exposed susceptible children is impractical. In sparsely settled rural communities some restrictions of susceptible household contacts may be justified. If the date of exposure can be reasonably established, an exposed susceptible may be allowed to attend school for the first seven days of the incubation period; otherwise, exclusion from school until 14 days from last exposure may be required.

During an epidemic it is not advisable to close schools and discontinue classes. Daily examination of the children by a physician or competent nurse should be provided. A nonimmune child presenting symptoms of coryza or cold or a temperature of  $99.5^{\circ}$  F should be placed under observation pending diagnosis. The principal justification for attempting to retard spread through a school population is to reduce the risk of carrying infection home to a family in which there is a child under three years of age.

Up to 92 per cent of the susceptible children exposed to intrafamilial contact may come down with the disease, depending upon their ages.

Immune globulin or immune serum should be made readily available. Its use should be restricted to children under three years of age, pregnant women, or children who are poor risks for any infectious disease because of poor health. In each case a physician should decide whether the objective of the prophylactic should be to modify the infection or to give complete protection. Services of visiting nurses should be made available, especially to the poorer families.

In a preventive program, institutions caring for infants and children should receive particular attention. Those responsible for the medical welfare of the inmates of such institutions should be fully acquainted with their responsibilities. Facilities adequate for the medical care of the maximum number of cases which might be expected in an outbreak should be made available in such manner as to avoid the hazards of crowding and cross infection. Provision for the segregation of infants is

Table 1-3. Measles attack rate among susceptible family contacts according to age

Age	Data of Fales (Baltimore)			Data of Top (Detroit)		
	Exposed Persons Without History of Previous Attack	Subsequent Cases in Family	Attack Rate Per 100 Susceptibles	Exposed Persons Without History of Previous Attack	Subsequent Cases in Family	Attack Rate Per 100 Susceptibles
Under 1 year	585	189	32.3	165	78	47.3
1 year	593	458	77.2	178	164	92.1
2 years	657	521	79.3	246	225	91.5
3 years	654	547	83.6	304	284	93.4
4 years	729	611	83.8	255	232	91.0

particularly important. Immunization with immune globulin of all the younger children who have not had measles may be of value in reducing the rapidity of spread and avoiding overcrowding in wards or dormitories used for the care of the sick.

GERMAN MEASLES

(*Rubella*)

German measles is an extremely mild eruptive fever which was separated as an entity distinct from scarlet fever and measles (rubeola) by Wagner, a German clinician, in 1829. Differentiation of these three diseases came slowly into practice; they are still confused at times. Rubella was considered unimportant until the brilliant observations of Gregg (1941) were made on the serious effects of the disease on the fetus in utero of pregnant females.

**Clinical Characteristics.** The incubation period is longer than in measles, 14 to 23 days, averaging about 18. Prodromal symptoms are slight and rarely last more than half a day; the rash may be the first symptom to attract attention. Swelling of the postauricular, suboccipital and cervical lymph nodes is one of the most constant features and an extremely useful one in establishing an early diagnosis. It may appear three to five days before the constitutional symptoms and eruption. In severe cases there may be a general lymphadenopathy, involving nodes in other parts of the body.

The character of the eruption varies somewhat but in most cases resembles that of measles more than that of any other disease. It spreads rapidly over the whole body and is composed of very small discrete maculopapules, pale red, and varying in size from a pin's head to a pea. Over the face they frequently become confluent. Sometimes there is a fairly uniform red blush over a large part of the body which bears a close resemblance to scarlet fever. About the time the eruption appears there may be a slight elevation of temperature—rarely exceeding 101.3° F. The course of the illness is a matter of one to three days; the lymph nodes may remain enlarged for some time afterward. Complications and sequelae are extremely rare.

**The Virus.** Hiro and Tasaka (1938) reported successful experimental transmission subcutaneously of the disease to children exposed to nasal washings filtered through a Berkefeld w. or Seitz, e.k. filters. Habel (1942) found *Macaca mulatta* monkeys to be susceptible to infection. He found virus in the blood up to 30 hours after the appearance of the rash. Filtered nasal washings were positive up to 24 hours. He isolated virus from one case without a rash. He was also successful in transmitting rubella to a monkey after five passages on the chorio-allantois of the chick embryo. He found no evidence of cross immunity with measles virus.

**Prevalence.** In its host relationships rubella resembles measles in that it is specifically dependent upon man for its survival. It is maintained in human populations by chain transmission from infected individuals to susceptibles. The infectious agent is contained in the nasopharyngeal secretions. The duration of the infectious period

has not been determined but Smith (1947) found it safe to allow children to return to school after four or five days from appearance of the rash. Susceptibility is general after the first few months of life until immunity is acquired. A considerable proportion of individuals become immune as a result of unrecognized or subclinical infection.

During epidemic prevalence many cases escape diagnosis and the disease receives little attention. It tends to prevail in widespread epidemics separated by longer intervals of time than in measles. Hence, it is more likely to have a somewhat older age distribution, although children are principally affected. The seasonal incidence of the disease is somewhat similar to that of measles.

**Relation to Congenital Defects.** The original observations on the relationship of rubella in the pregnant mother to the occurrence of congenital defects in the infant were made by Gregg and others in Australia (1945). His observations have since been confirmed and extended by many investigators. In the Australian studies it was found that of all the congenital defects, microcephaly (74 per cent) and deafness with secondary mutism (69 per cent) were the most frequent, cardiac malformations (39 per cent) and eye defects, particularly cataracts (17 per cent), following in that order. Later studies in the United States and in England have increased the number of specific defects which were attributed to this cause to include dental abnormalities, clubfoot, cleft palate, spina bifida, and others. There seems to be general agreement that infection of the mother is most dangerous in the first two months of pregnancy. The risk decreases when the infection occurs during the third month and after the fourth month there appears to be little danger. There is no relationship between the severity of the maternal infection and the nature of the defect. The Australian studies suggest that malformations and defects may occur in 90 per cent and more of infants (Swan and others, 1946); more recent American studies, made under somewhat different conditions (Ingalls and Gordon, 1947; Ober and others, 1947), estimate that they occur in about 50 per cent of infants born to mothers who have rubella in the first three months of pregnancy. So definitely has this relationship been established that it is considered to be an indication for therapeutic abortion. In assisting the pregnant woman to come to a decision regarding therapeutic abortion following rubella infection, the physician should bring to her attention the consideration that the chance of a congenitally abnormal child is substantial. A young woman or one with several other children may elect to terminate a particular pregnancy complicated with rubella. On the other hand, an older woman in her first pregnancy may wish to accept and continue to term.

**Control Measures.** There is no evidence that the spread of rubella in a community can be prevented by isolation of cases and restrictions made upon susceptible contacts. The disease is infectious before diagnosis can be made. There are a great many unrecognized and subclinical infections. It is so mild that a great proportion of cases never come to medical attention. Exposure is inevitable. The only protection is immunity acquired through attack. This immunity can be acquired without penalty, provided it does not occur in the female during the childbearing period. Control measures are accordingly concentrated upon protecting the pregnant female. It is desirable that every girl should have rubella before reaching the childbearing period. Expectant mothers should be informed concerning the danger if they have never had rubella or if the matter is in doubt because of faulty diagnosis and every

effort should be made to protect her from exposure to this disease if it is known to be occurring in the vicinity. If, despite precautions, she has a known exposure, prophylaxis with immune globulin as in measles should be attempted even though its value has not yet been definitely established. In the event that a woman develops rubella during the first four months of her pregnancy, the artificial termination of the pregnancy should be considered by the consulting obstetrician.

#### MUMPS

##### (Epidemic Parotitis)

Mumps was one of the first common contagious diseases to be differentiated. It was described by Hippocrates as a mild epidemic sickness characterized by non-suppurative swellings near the ears and occasionally accompanied by enlargement of the testes. With recognition that it is primarily an involvement of the parotid glands, the disease has commonly been called epidemic parotitis.

**Clinical Manifestations.** The infectious process may affect not only the salivary glands, the pancreas, testes and ovary, but also extend to the central nervous system and other organs. A fatal termination, however, is extremely rare.

In the milder cases the local symptoms are the first to attract attention. There is pain in the region of the parotid, increased by movements of the jaw, by pressure, and sometimes by the presence of acid substances in the mouth. In the more severe cases constitutional symptoms as fever, headache, vomiting, pains in the back of the limbs, may precede by 24 to 48 hours pain and swelling in one or both parotid. Occasionally, swelling of the submaxillary or sublingual glands occurs before that of the parotid, and in rare instances these may be the only glands affected. The constitutional symptoms usually last from three to five days, the swelling subsides slowly over the ensuing one or two weeks. Symptoms of extension to other structures usually develop from four to seven days after onset of the parotitis, when this swelling is beginning to subside. Occasionally, involvement of the salivary glands is minimal or unnoticed and the clinical manifestations are due to invasion of the testes, ovaries, pancreas or central nervous system.

Among males from 15 to 25 years orchitis is a common complication, occurring

in one out of every four or five cases. The affected testes may undergo atrophy to some extent but complete sterility seldom ensues owing to the rarity of bilateral involvement. The analogous infection of the ovaries (ovaritis) in mature females is much less frequent. Involvement of the pancreas, which is still less frequent, is indicated by persistent nausea, abdominal pain, and tenderness.

Estimates of the frequency of meningo-encephalitis range from 0.5 to 10 per cent of the cases of parotitis. Symptoms vary in pattern and severity from those of a mild meningitis to those of a severe encephalitis. It seems not unlikely that there is an increase in the lymphocytes in the cerebrospinal fluid in a large proportion of cases of mumps whether there is definite clinical evidence of meningeal involvement or not. Mumps meningo-encephalitis without parotitis is by no means rare. Kilham and others (1949) have recently called attention to the possible confusion of this condition with nonparalytic poliomyelitis.

Johnson and Goodpasture (1935) proved conclusively that mumps is due to a filtrable virus which is present in the saliva, at least in the early stages of the disease, and capable of producing a comparable parotitis in *Macaca mulatta* monkeys when inoculated directly into Stensen's ducts.

The susceptibility of monkeys (species *Macaca*) to mumps infection was confirmed by later workers. In 1942, Enders and Cohn described a complement-fixation reaction employing an extract of infected monkey parotid glands as virus antigen, and in the following year the use of this same antigenic material in a skin test for susceptibility to mumps. A more available source of antigen was required before these tools could be put to practical use. It came when Karl Habel (1945) reported cultivation of mumps virus in developing chick embryos. This was confirmed and extended by Levens and Enders (1945) who demonstrated that the virus was principally concentrated in amniotic sac material. The way was thus opened for advancement of studies of the properties of the virus itself and of immunological methods designed to recover and identify the virus, to provide diagnostic tests and to determine susceptibility and immunity.

The infective particle in allantoic fluid of the chick embryo is probably in the range of 90 to 135 *mu*. It is inactivated by heating for 20 minutes at temperatures of 55° to 60° C and infectivity is lost within 12 hours after the addition of 0.1 per cent formalin, or by appropriate irradiation with ultraviolet light. The virus, like that of influenza and Newcastle disease, possesses the property of agglutinating chicken erythrocytes. This hemagglutinating activity is specifically inhibited by high dilutions of serum of man and rhesus monkeys convalescent from mumps (Robbins and others, 1949). A practical technic has been devised which permits demonstration of development of specific antihemagglutinin in human or monkey sera. Similarly, amniotic fluid provides a source of antigens for use in a complement-fixation test (Henle and others, 1948). Both antihemagglutinin and complement-fixing antibodies appear in the blood early in the disease and reach maximum titers the second or third week. An increase in titer by a factor of 4 or more has diagnostic significance with either test. Immune sera also possess the property of neutralizing virus in the mixtures incubated and inoculated into allantoic sac of eggs (8-day embryos) (Habel, 1951).

The use of inactivated mumps virus antigen in allantoic fluid as a skin test has been explored (Habel, 1952; Henle and others, 1951). This technic is a research procedure and has not yet been standardized. A high degree of correlation

has been found between the positive skin test and the positive complement-fixation test. From 70 to 80 per cent of individuals giving a history of having had mumps are positive by one test or the other. Neither a positive complement-fixation reaction nor a positive skin response affords absolute assurance of resistance to mumps, but the incidence of infection among such individuals was found to be less than 2 per cent, whereas, under the same conditions of exposure, it was many times that in those giving negative reactions. From 17 to 27 per cent of individuals with negative histories gave either positive complement-fixation reaction or positive skin test, or both. This was interpreted as evidence of inapparent, unrecognized or abortive infections in the past or of defective memory.

**Vaccine.** Commercial vaccine is prepared from the allantoic fluid of chick embryos infected with a single strain of mumps virus. After inactivation of the virus with formaldehyde the vaccine is standardized with respect to immunizing potency. Reactions, if they occur at all, are usually mild and do not last more than 24 hours. The degree and duration of protection afforded by inactivated mumps vaccine of this type has not been determined. In a large scale experiment conducted by Habel (1951) there was evidence that the attack rate of mumps was consistently lower in the vaccinated than in the nonvaccinated comparable control groups.

**Prevalence.** The only known source of mumps virus is the saliva of an infected human being. The virus is probably present in the saliva from about 6 days before the onset of parotitis until about 9 days after. On the basis of studies made with the complement-fixation reaction, inapparent or unrecognized infections are not uncommon. The incubation period varies from about 12 to 26 days, most commonly about 18 days. Susceptibility begins in early childhood, although infants rarely have a clinical attack. Immunity following an infection is usually durable, second attacks are extremely rare. The age distribution of cases of mumps is somewhat older than that of the other common contagious diseases. Maximum incidence occurs in about the eighth or ninth year. When the age of 20 is reached about 60 per cent of individuals give a history of having had mumps. It is not unusual for individuals to escape infection until young adult life.

When introduced into a residential school or a military organization the infection spreads slowly and insidiously. During World War I there were 230,356 cases of mumps, as compared with 96,817 cases of measles, among 4,000,000 men in the U. S. Army. The noneffective rate for mumps was the third highest for all diseases, being exceeded only by the rates for influenza and gonorrhea. During World War II this disease was of much less importance among Army troops. This was not surprising in view of the tremendous increase in travel in this country resulting in decreasing isolation of rural areas where many persons formerly reached adult life without having had mumps. According to McGuinness and Gall (1944) epidemics occurred principally among groups of soldiers from the rural areas of the south and southwest. About one third of the patients were moderately to seriously ill with orchitis or meningo-encephalitis, both of which occurred in some instances without an associated parotitis.

**Control.** Because of the communicability in the early stages before diagnosis can be established, of the indefinite duration of the infective period, of the common occurrence of mild, ambulatory and missed cases, the spread of mumps cannot be prevented under ordinary circumstances. It is customary in most communities to isolate cases of the recognized disease until swelling of the salivary glands has sub-

sided. In schools and institutional groups it may be desirable to attempt to retard dissemination by restrictions placed upon exposed susceptible contacts. Such contacts may be permitted to attend classes for ten days following the date of earliest exposure and excluded for a two-week period thereafter. However, the opinion is held with equal cogency that to attempt to prevent infection with mumps during childhood is a disservice. The disease tends to be more severe in adult life and carries with it the risk of sterility. According to this view, there is no good reason for trying to interfere with natural exposure. Vaccination would seem to be indicated for susceptible parents who may be exposed to infected children and adults in institutional, labor, industrial or other special groups among whom the disease may become epidemic. The value of the use of immune serum or immune globulin has not been established. A study made during World War II by Gellis and others (1945) led to the conclusion that gamma globulin derived from pools of normal human plasma administered to patients with parotitis of 24 hours duration or less was ineffective in reducing the incidence of orchitis complicating mumps in the dosage used (5 ml.), whereas gamma globulin (20 ml.) from mumps convalescent serum appeared to be highly effective in this respect.

#### COMMON RESPIRATORY DISEASES

##### *(Acute Minor Respiratory Infections)*

A number of diseases have been grouped together under the designation common respiratory diseases or acute respiratory infections. Progress has been made in recent years in separating out of this group some of the entities of which it is composed. Some still cannot be readily identified. Their symptomatology is so protean as not to permit differentiation. The tissues of the respiratory tract have a limited capacity to react defensively against noxious agents. The area or areas of the mucous membrane which are involved exhibit some measure of congestion, edema, altered

secretory activity of mucosal cells, outpouring of leukocytes and, in some instances, cellular destruction in the formation of an inflammatory membrane. An indication of this process is a nasal discharge usually thin and serous at first, sometimes viscid and frequently becoming mucopurulent. Subjectively, the individual experiences indisposition, lassitude, headache, chilliness, fever, general aching, weakness and prostration, with varying intensity. Sneezing and dry or productive cough may or may not come into play as a clearing mechanism. The process occasionally goes on to the involvement of the terminal bronchioles and alveoli of the lungs. Thus, the clinical pattern shows an endless variation both as to the areas of principal involvement and severity of symptoms. These patterns have frequently been designated by anatomical reference as rhinitis (coryza), pharyngitis, tonsillitis, tracheitis, bronchitis and pneumonitis (pneumonia), or some combination of these.

Much more satisfactory, though difficult, is a classification based on etiology. By careful observation and description and the use of laboratory procedures, one after another of the causes have been identified but many still remain to be determined. In general, the known causes may be grouped as noninfectious and infectious agents.

The noninfectious agents are physical, chemical, and nervous stimuli. It is a common experience that the nose becomes congested in a warm stuffy room; it secretes mucus freely, "runs" on a cold day. Engorgement of the mucous membrane can be reproduced as a result of the reflex nervous stimuli. Mudd and Grant (1919) have shown that chilling of the skin causes vasomotor contraction and ischemia of the mucous membrane of the tonsils, palate, and pharynx, as well as the skin, with a drop in temperature and a subsequent increase in bacteria on these parts. On rewarming the subject, the tonsils tend quickly to recover their blood supply, and in some instances actually become hyperemic; the skin returns to about its normal condition, but the palate and pharynx remain somewhat ischemic. An irritating gas, such as chlorine, will cause profuse lacrimation and nasal discharge with irritative cough. The dusty atmosphere of a barn at haying time will produce much the same effect. "Rose cold" or hayfever is a manifestation of allergy initiated by contact of the respiratory mucous membrane with antigens, contaminating pollens and dusts, causing asthma when the reaction involves the bronchioles. With the exception of hayfever and asthma, reactions to these physical, chemical, and nervous stimuli are usually of relatively brief duration. They are, nevertheless, frequently classified as "colds." In no small measure they are responsible for the reputation of miraculous remedies which advertisements claim cure a cold "if taken early enough."

More important are the biologic agents, the microparasites of various genera and species which are capable of initiating an infectious process on the mucous membrane of the upper respiratory tract. Against many of these the evidence is clear cut and definite. Some have been only partially incriminated in their causative role. Others remain yet to be discovered. Differential diagnosis depends not only on the epidemiological and clinical pattern but very largely upon diagnostic laboratory procedures, which are not always readily available. Due consideration is always given first to the possibility that an acute respiratory illness in an individual is the beginning of, or a mild clinical attack of, some well known disease, for example, whooping cough, diphtheria, measles, streptococcal sore throat. More rarely, and in certain limited areas, consideration must be given to more unusual diseases, such as "Q" fever, coccidioidomycosis, psittacosis, acute lymphocytic choriomeningitis.

Among the first and foremost agents which have been proved to be the cause of acute respiratory disease are the influenza viruses. Recently, it has been appreciated that these viruses are responsible not only for epidemics but also to some extent for the endemic occurrence of acute respiratory disease.

When the known causes have been excluded from consideration, there remains a large number of acute respiratory infections, the causes of which are in the process of delineation. It has recently been suggested (Dingle, 1948) that this group be divided tentatively into four categories which may represent separate etiologic entities, namely, the "common cold," nonbacterial exudative pharyngitis and tonsillitis, acute respiratory disease undifferentiated or "ARD," and primary atypical pneumonia.

### COMMON COLD

In reviewing previous work on the "common cold" one must constantly keep in mind that the definition of this condition has varied widely (Thompson and Thompson, 1932). In the older literature it was a much more inclusive designation than it is today. It is now defined as a mild, self-limited, afebrile respiratory illness, characterized by catarrhal inflammation of the mucous membranes of the nose, the sinuses and contiguous structures of the upper respiratory passages. The prominent features are coryza, lacrimation, conjunctivitis, dry and scratchy throat, an irritative cough, swollen and congested mucous membranes, and a normal leukocyte count. But considerable clinical variations are seen in "colds" as they occur in different persons and in the same person at different times. Some appear to be localized in the nose and sinuses or the throat; others, regardless of the area of initial involvement, spread to infect almost the entire respiratory tract. Some are mild without systemic reactions; others are more severe, with associated fever, chilliness, malaise, and other constitutional symptoms. Clinically, then, diagnosis of the "common cold" encompasses illnesses which may represent variations of a single disease entity or which may be due to multiple agents.

**Etiology.** The investigations of Kruse (1914), Foster (1917), Dochez and others (1930), Long and others (1931), demonstrated that coryzal types of illness of a short period of incubation could be transmitted to well human beings and chimpanzees by inoculation of bacteria-free washings of the respiratory tract of patients with colds. Investigations of the Commission on Acute Respiratory Diseases (1947a, b) have confirmed and extended these studies. Andrewes and his associates (1949) have more recently reported the results of a large series of human experiments carried out under carefully controlled conditions.

**Characteristics of Cold Viruses.** Filtration experiments (Andrewes, 1949) suggest that one infective particle, presumably a virus—20 to 50 $\mu$  or less—is considerably smaller than the influenza virus particle. These filtrates suffered no demonstrable loss of infectivity for human subjects on storage in sealed ampules in dry ice at  $-76^{\circ}\text{C}$  for two years; at  $10^{\circ}\text{C}$  they survived at least 27 days, and at  $4^{\circ}\text{C}$  for three days.

Aside from the chimpanzee no other animal has been found that is susceptible to infection with cold virus. Andrewes and his associates (1949) have attempted in vain to produce colds in mice, rats, guinea pigs, cotton rats, voles, rabbits, hamsters, grey squirrels, hedgehogs, ferrets, kittens, parrots, chickens, pigs, green monkeys, red patas monkeys, capuchin monkeys, and sooty mangabey.

There have been many attempts to grow cold virus in tissue culture. Ward and Proctor (1950), in three controlled experiments, found that signs and symptoms similar to those of the common cold developed in 14 of 23 individuals receiving virus material isolated from human sources and transmitted through the allantoic sac of the chick embryo for five passages. On the other hand, in extensive trial Andrewes and his collaborators (1949) were unsuccessful in attempts to pass the virus in fertile hen's eggs.

The complications of the common cold—sinusitis, adenitis, bronchopneumonia—are caused by secondary invasion of the inflamed mucous membranes by the bacteria which happen to be present in the upper respiratory tract—streptococcus, staphylococcus, pneumococcus, influenza bacilli.

**Observations on Experimental Colds.** From observations made upon experimental colds produced in human beings by Andrewes in 1949, the incubation period was normally two or three days, with a range of one to six days. Nasal discharge was an almost invariable symptom, was usually thin and serous at first, but sometimes viscid from the beginning. Twenty-four hours after onset it was commonly mucopurulent. Malaise and headache were common at the onset, but fever was exceptional. About one third had cough, usually unproductive. Postnasal discharge was uncommon; so were complications. The symptoms were rather mild and of brief duration, usually less than six days. The infectious agent was found in nasal secretions 24 hours before the first symptoms of the cold. How long it may persist has not yet been determined. There is no direct evidence that cold viruses can survive long outside the body.

**Immunity to Cold Viruses.** The Commission on Acute Respiratory Disease (1947b), inoculated five volunteers with a cold virus and produced colds in four of them. Meanwhile, they stored some of the same virus until 19 days later when these colds had cleared, they then used the stored virus to challenge the immunity of the same five persons. Again, four out of five developed colds; one who had resisted the first inoculation this time was a victim. This result does not necessarily mean that immunity to colds is so short under natural conditions. The dose of virus given experimentally was probably many thousand times as big as any conceivable natural dose. In Andrewes' experience, about 40 per cent of volunteers who were experimentally exposed to a cold virus proved to be resistant, though hardly any of them claimed to be free from colds throughout the year. Many observations attest that the resistance to colds in individuals varies from year to year (Gafafer and Doull, 1933) and for no apparent reason. Some individuals may have colds each year, others have none. The available evidence suggests that resistance acquired through having experienced an infectious cold is of variable degree and duration.

**Predisposing Causes.** It has long been assumed that colds are induced in those who are "run down," fatigued and exposed, with depressed vitality due to poor hygiene, loss of sleep, insufficient food and other depressing influences. Lesions of the mucous membrane, deviated septum, and other malformations, enlarged tonsils, adenoids and polypi, are all set down as inviting congestion and infection, in short, predisposing to colds. However, when the subject is studied, no particular significance seems to attach to these factors. Thus, according to Gafafer (1932), those with tonsils and adenoids and those without tonsils and adenoids present no significant difference with respect to frequency, severity or type of attack. A study by the same investigator of groups with brown eyes and with blue eyes showed no significant

differences; and the same is true of groups of Jews and non-Jews. Palmer found no evidence of association between size of frontal sinus and the number and duration of attacks. Doull and others (1931) presented an analysis of the frequency and severity of attacks in persons classified, on otolaryngological examination, as normal and abnormal with respect to tonsils, adenoids, breathing space, turbinates and maxillary sinuses. Taken as a group, individuals exhibiting one or more abnormalities were found not to suffer a greater frequency of attack than normal persons. Hardening procedures, such as sleeping with windows open and exercising outdoors, appear to exert no significant effect. A study of the effect of irradiation with ultra-violet light by Doull and others (1931) gave a slightly higher incidence for the irradiated group, and severe cases were just as frequent in the irradiated as in the control group. There is no convincing evidence that drafts produce an infectious cold.

To summarize, very little is known about the factors which depress resistance to the common cold.

**A. P. C. Viruses.** Hilleman and Werner in 1949 reported recovery of a hitherto unknown viral agent, designated as RI-67, from throat washings of a patient suffering from an acute respiratory illness. It grew and caused characteristic cytopathogenic changes in tissue culture containing human epidermoid carcinoma (HeLa) cells. Similar but antigenically different strains were isolated by this technic in other outbreaks of respiratory disease (Huebner and others, 1954). These strains have been called the A. P. C. (adenoidal-pharyngeal-conjunctival) group. Six types have been recognized. The pathogenic potentialities to the human host are being explored.

**Mode of Transmission.** The virus is present in the secretions of the upper respiratory tract during the early stages of a cold. The infection is presumably conveyed from person to person by coughing, sneezing, and talking. The relative importance of conveyance by droplets, by contaminated articles and by air-borne droplet nuclei, is unknown. It is attested by Arctic explorers that conversational contact in the open air is sufficient to effect transmission.

**Prevalence and Distribution.** According to Kneeland and Dawes (1932) during the first few months of life colds are relatively infrequent, perhaps because of protected existence. Gradually, their frequency increases. Maximum frequency occurs during the second year and remains at a high level under five. The incidence gradually declines throughout childhood to reach a more or less stable level experienced during adult life. In Baltimore studies by Van Volkenburgh and Frost (1933), the attack rate per 100 persons at all ages observed for one year was 307. This is in approximate agreement with the findings of other observers that about three colds in one year is average experience.

At times colds spread through whole families in rapid succession. At other times a single member of the family is affected and there is no further spread to associates.

Limited data are available which permit a comparison of the frequency of the common cold in populations otherwise comparable but living in different latitudes. The nearest approach to this is the study of Frost and Gover (1932) of acute minor respiratory disease in civil population groups in the United States. The data collected at that time suggested that there was very little difference in the experience of the population surveyed in communities of such wide geographic distribution as Washington, Baltimore, New Orleans, and San Francisco. Attempts to relate the

incidence of colds directly to temperature, rainfall, humidity, and sunshine have not been convincing. On the other hand, there is much evidence to indicate that in the North Temperate Zone the prevalence of minor respiratory infections shows a distinct seasonal pattern. If the experience of the U. S. Army can be taken as representative, the curve shown in Figure 1-4 indicates the annual cycle of respiratory disease incidence. The rates are based on cases per 1,000 strength per year for common respiratory disease and influenza combined. Highest incidence is reached in the winter months between December and April; lowest frequency is registered in the summer months from June to September (Health of the Army, 1947). This

Fig. 1-4. Annual cycle of respiratory disease incidence, United States, January 1924-January 1947. Comparison of the synthetic annual cycle with the date (after smoothing) from which it was derived.

Note: Ordinates are rates in cases per thousand strength per year for common respiratory disease and influenza combined.

is a smooth curve obtained from a very large experience extending over 23 years. From the character of this seasonal curve, the inference may be drawn that the conditions of living during the colder months of the year are more favorable to the dissemination of acute respiratory diseases.

Colds normally cease to trouble an isolated group, such as a band of Arctic explorers soon after they left civilization behind. Smillie and his associates and Paul and Freese (1933) studied common colds in isolated places, such as the Northwest River, Labrador, and Spitzbergen, Norway. The natives are susceptible but free from colds until the arrival of a stranger or ship. Once introduced the infection spreads widely, but disappears at the end of the open season. In Tristan da Cunha, visiting ships bring with them epidemics of colds, but these are brought only by ships from Capetown, the voyage from which lasts not more than 12 days. Ships coming from Panama around Cape Horn do not bring colds; perhaps the virus normally dies out

within a few weeks (Andrewes, 1949). These observations suggest that there are no inapparent infections of long duration or carriers who harbor the viruses from one season to another, at least in these subarctic regions.

In communities, civil, military and institutional, which are affected by the ordinary travel and intercommunication of people, the seasonal rise and fall in the incidence of colds is characterized by a series of oscillations due to a succession of epidemic periods of varying magnitude (Van Volkenburgh and Frost, 1933). In studies of the residential schools in England (School Epidemics Committee, 1938) data were presented to indicate that quite uniformly there were epidemic peaks in the incidence of minor nasopharyngeal infections from two to four weeks following reaggregation of students after a holiday period spent at home.

**Prevention.** Exposure to the infectious agents which cause the common cold is unavoidable for all who live within the bounds of civilization. The frequency of such exposure is modified by habits of living and environmental circumstances. It is apparently greater during the colder and more inclement months of the year when people are brought together in groups or crowds within doors a greater proportion of the time under conditions of poor ventilation. The possibilities of prevention by disinfection of indoor air are discussed in the next chapter.

One would expect that in a community in which a high level of personal hygiene prevails with regard to coughing, spitting, sneezing and use of handkerchiefs, and in which a high degree of cleanliness is maintained with respect to hand washing, and washing of common drinking glasses, dishes, eating utensils and other commonly used objects, that there would be some reduction in transmission. Up to the present, however, there has been no conclusive demonstration that this is true.

Courtesy requires that the individual who has a cold have regard for his fellow and take all reasonable precautions to prevent dissemination. On the other hand, it is humanly impossible that constant vigilance be maintained in this matter, even by individuals who are fully cognizant of the ways and means of transmission. So far as present knowledge permits statement, a mild cold or one in its incipency, causing practically no inconvenience, may be as infectious as a severe cold with sufficient constitutional reaction to require bed treatment.

**Chemoprophylaxis and Treatment.** Suppression or modification of the infectious type of common cold by the administration of drugs is a subject about which much has been written and little been scientifically proved. The Committee on Public Health Relations (1951) has advised that the value of antihistaminic drugs in treating the common cold is negligible. Discrete treatment with antibiotics may in some measure reduce the incidence of secondary bacterial complications. Other measures may make the patient more comfortable.

**Cold Vaccines.** During the era when the common cold was thought to be due to the bacteria commonly found in the upper respiratory tract, much was written on the subject of prophylaxis by vaccines. These were made from single or mixed strains from stock or autogenous cultures. They contained staphylococci, streptococci, micrococcus catarrhalis, Pfeiffer's bacilli, pneumococci, and other organisms. Where the observations were carefully controlled there has been no convincing evidence that they were of value (Diehl and others, 1940).

The development of an immunizing procedure based upon the use of preparations of the virus or viruses which are thought to cause the common cold is distinctly in the realm of experimental study.

## EXUDATIVE TONSILLITIS AND PHARYNGITIS OF UNKNOWN CAUSE

Differentiated from the common cold on one hand and from streptococcus sore throat on the other, this is a clinical condition tentatively identified as "exudative tonsillitis and pharyngitis of unknown etiology" (Commission on Acute Respiratory

Diseases, 1947a). This differentiation has been suggested by a number of investigators (Stuart-Harris and others, 1938; Francis, 1939; Keith and Carpenter, 1946). It is generally a mild disease of short duration. The onset is ordinarily gradual, and early complaints in the majority of patients are those of feverishness, headache, and anorexia. Symptoms of sore throat, hoarseness and cough, often productive, are noted by 75 per cent or more of the patients and tend to reach great prevalence by the third or fourth day of the illness. Nasal symptoms are not common. On physical examination, the mucous membranes of the palate, the pharyngeal wall and tonsils show varying degrees of injection, which is usually not severe. The exudate is usually small in amount and appears as gray or yellowish individual spots which are pinhead in size. Larger patches of exudate may develop, but rarely do they become confluent. Often the exudate forms over swollen lymphoid follicles on the pharyngeal wall. Enlargement of the cervical lymph nodes may be present in approximately one fourth of the cases. Involvement of the lungs occasionally occurs. In approximately two thirds of the cases total leukocyte counts are below 10,000 and the differential formulas are normal. Bacteriologic and serologic examinations give no evidence of beta hemolytic streptococcus infection. The average peak of temperature is between 101° and 102° F, and the fever ordinarily declines by lysis. The duration is approximately five days and convalescence is usually uneventful. The cause of this syndrome has not been determined nor have direct attempts been made to transmit the infection to man. At the present time, the disease can be diagnosed only after the exclusion of the common bacterial infections, by clinical, cultural and serologic methods. The problems of prevention are essentially similar to those of the common cold.

#### UNDIFFERENTIATED ACUTE RESPIRATORY DISEASE

On the basis of experience during World War II, the Commission on Acute Respiratory Diseases (1947b) proposed that a category designated as undifferentiated respiratory disease be tentatively recognized as clinically, immunologically, and epidemiologically distinct from the common cold and influenza. As seen in hospitalized recruits, it is a mild respiratory illness with gradual onset. Most frequent complaints are those of feverishness, chilliness, and headache. Symptoms of malaise, anorexia and nasal involvement appeared in approximately one-half the patients. Sore throat is common but is mild in degree in comparison with that encountered in patients having exudate in the throat. Minimal hoarseness and cough are common, although fewer than half of the patients have productive cough or pain in the chest. On physical examination, the patient rarely appears to be severely or even moderately ill. Physical signs are remarkably few and are usually noted in less than half the patients. Nasal obstruction, mild injection of the pharynx and palate, and lymphoid hyperplasia on the pharyngeal wall are most frequently found. Edema of the mucous membranes, cervical adenopathy and thoracic rales are present in approximately 10 per cent of the patients. The febrile course is short, from two to four days, and the average maximum temperature is about 101° F. Constitutional symptoms subside with defervescence, but symptoms referable to the respiratory tract when present, tend to persist for one or two weeks. Leukocyte counts are usually within normal limits, and cultures of the throat reveal only normal bacterial flora.

It appears, therefore, that this syndrome may be a clinical entity of nonbacterial

origin, which differs from the common cold or acute coryza. Mild respiratory illnesses exhibiting similar characteristics have been produced in human volunteers as a result of exposure to throat washings from a representative donor (Commission on Acute Respiratory Diseases, 1947c). Reinoculation of experimental subjects with filtered washings from the same donor produced no illness. It thus appeared that undifferentiated acute respiratory disease in contrast with the common cold is followed by homologous active immunity. Success of inoculation of these experimental subjects at later periods with filtered throat washings from a patient with severe common cold and from a patient with atypical pneumonia, however, failed to demonstrate heterologous immunity to the agents producing the two latter types of respiratory disease. This study in human volunteers indicates that a mild disease of the respiratory tract, characterized by an incubation period of five or six days, and a predominance of pharyngeal symptoms and signs can be transmitted to man. This disease not only has a longer period of incubation than the common cold but also appears to be immunologically distinct. The causative agent is filtrable and is presumed to be a virus.

This condition was further differentiated upon epidemiological evidence (Commission on Acute Respiratory Diseases, 1946). It appears to be the condition which is largely responsible for acute respiratory disease in recruits (Sartwell, 1951). When recruits are brought together in training units during the early winter and spring months, an epidemic spread of this condition, reaching its peak usually in the third or fourth week of formation of the training unit is a common experience. The rates among recruits are several times as high as those among seasoned troops. When recruits are brought together for training purposes during the summer and early fall these epidemics do not ordinarily occur.

**Prevention.** The problems of prevention are those of the prevention of acute respiratory infections in general. They are discussed in Chapter 2. The results of antibiotic treatment are equivocal.

#### PRIMARY ATYPICAL PNEUMONIA, ETIOLOGY UNKNOWN

(*Virus Pneumonia, Acute Pneumonitis*)

During recent years, there has been an increasing interest in the occurrence of cases of respiratory infection associated with pulmonary lesions in which the common pathogenic bacteria do not seem to play any etiologic role. The name "virus"

pneumonia has been applied rather loosely to this group. This designation, however, would include pneumonia occurring in the course of such well known diseases as measles, smallpox, psittacosis, or influenza. Excluding these from consideration, there remains a syndrome which appears to be clinically and epidemiologically distinct but which may have a multiple etiology. Until etiology is clarified and more specific diagnostic laboratory tests become available, it is proposed that this syndrome be designated as "primary atypical pneumonia of unknown etiology." The infectious process does not always involve the pulmonary area and in its milder manifestations in individuals is indistinguishable from the common cold and acute undifferentiated respiratory disease.

There is no reason to believe that this is a new syndrome. In its more severe manifestations, as a form of pneumonia, it was described clinically and pathologically as long ago as 1872 (Dingle and Finland, 1942). Since that time it has been designated variously as "acute influenzal pneumonia," "acute pneumonitis," "acute interstitial pneumonitis," "atypical pneumonia with leukopenia," "atypical bronchopneumonia of unknown etiology."

**Clinical Characteristics.** This syndrome is characterized by gradual onset and benign course. In some patients the constitutional symptoms—headache, chilliness, malaise, fatigue—are prominent in the early stages of the illness and gradually increase in severity. In others, the illness begins as a localized infection of the respiratory tract as indicated by dryness and soreness of the throat, and by cough. Coryza may be noted in about one third of the cases. As the disease progresses, the cough ordinarily becomes productive of greenish yellow mucopurulent sputum. Rarely is the sputum mixed with blood. Physical examination early in the illness usually reveals little beyond mild infection of the pharynx. Later, however, medium fine, sticky rales and coarse rales are characteristically heard in the involved area of the lung. X-ray examination provides evidence of pulmonary involvement. Infiltration is usually light and patchy and peribronchial in distribution. The x-ray shadows may be migratory. The average illness is about five to seven days' duration. Complications are infrequent and the prognosis is excellent despite the lack of specific therapy. The uncomplicated pneumonia is rarely fatal. The case fatality rate is estimated to be less than 0.1 per cent.

**Etiology.** The causation of primary atypical pneumonia was extensively investigated in a number of laboratories during World War II. Attempts to establish in animals an infection which could be related immunologically to the human disease had for the most part been unsuccessful. Studies of the Commission on Acute Respiratory Diseases of the U. S. Army (1946 and 1947a, b), demonstrated that primary atypical pneumonia can be transmitted to human volunteers by bacteria-free filtrate of sputum and throat washings. Clinically, the experimentally induced infections resembled the naturally acquired disease. The incubation period was from seven to 14 days. There was no evidence that bacteria played any part in initiating the infection or as secondary invaders. Thus, clinical and experimental evidence indicate that primary atypical pneumonia is a virus infection of the respiratory tract. Further investigation is necessary, however, to determine whether or not one agent or more is concerned in the production of the naturally acquired disease.

**Laboratory Diagnosis.** It is necessary to exclude first, by appropriate diagnostic procedures, other diseases which may present essentially the same syndrome. The

diagnosis is established partly by exclusion of other causes. However, two empiric laboratory tests have proved to be of some value. Both are agglutination reactions in which the acute and convalescent specimens of the patient's serum are examined in order to demonstrate a rise in antibody.

The first, or cold agglutination test, utilizes O human red blood cells as antigen. Agglutination takes place only at a cold, usually icebox, temperature. On warming to 37° C the hemagglutinin disappears. The second test is the agglutination of streptococcus MG which is carried out in essentially the same fashion as other agglutination tests. The proportion of patients whose sera show significant increases in titer for one or the other of these agglutinating antibodies, or for both, has varied in several reports of a series of cases. In general, approximately 50 per cent of the patients show positive reactions. The two tests appear to be directly correlated with the severity of the illness and the extent of pulmonary involvement. Each provides a retrospective confirmation of diagnosis of primary atypical pneumonia, since the antibodies do not develop until the second or third week of illness. Moreover, failure to demonstrate antibodies does not exclude the diagnosis.

**Occurrence.** As pointed out by Francis (1944), the apparent increase in the frequency of this form of pneumonia has been due to a number of developments in recent years. The greater use of the laboratory in identifying the bacterial agents in cases of pneumonia by pneumococcus typings and cultures of the sputum or blood has revealed an increasing number of cases in which significant bacterial agents were not encountered. The widespread use of chemotherapy and recognition of the prompt response of pneumococcal and streptococcal pneumonia to sulfonamides suggested that processes that did not respond were of different etiology. There has been a reduced incidence of pneumonia due to pneumococcus. Last, and perhaps most important, the availability of x-rays in establishments where large groups of individuals are drawn together, as in schools, industry, military forces, has aided in the recognition of pulmonary involvement in many instances which could not be so interpreted on the basis of physical examination or clinical course. The differentiation of this disease from other acute respiratory infections depends very largely upon characteristic x-ray evidence. Because of these considerations, data regarding the occurrence of this syndrome are meager and fragmentary. Except for certain limited studies, its distribution is largely unknown. These studies have come very largely from Army camps, schools, and colleges.

From these accounts it seems that primary atypical pneumonia is characteristically sporadic in occurrence but at times becomes so frequent as to constitute epidemics. The following accounts are illustrative. Bowen in 1935 discovered a yearly attack rate which varied from less than one to approximately six per 1,000 in white troops during a three-year period, in Honolulu. Reimann and Havens (1940) observed 25 cases among a hospital staff of 813 persons. Smiley and others (1939) reported an incidence at Cornell University of approximately 9 in 1,000 for the academic year 1937-38. Gallagher (1941) reported an epidemic of 87 cases among adolescents. Daniels (1942) reported 13 cases in a school of about 90 girls, during a six-week period, or almost 15 per cent.

Many of the observers remarked upon the occurrence of mild respiratory disease without pulmonary lesions demonstrable by x-ray in persons associated with atypical pneumonia. Reimann (1938) noted that in a group of five patients who had house-

hold contact there were two cases of severe infection and three with mild illnesses which might have been called common cold or febrile catarrh. In the epidemic at Jefferson Hospital, Reimann and Havens (1940) describe 407 cases of respiratory disease in a staff of 813. By far the largest proportion (75 per cent) of these were mild infections, and the patients remained ambulatory. About 100 were sick enough to go to bed. Clinical and roentgenological diagnosis of acute tracheobronchitis was made in 25 and of pneumonia in 25. Apparently cases of the mild form (nasopharyngeal laryngitis), 88 per cent, far outnumbered those of the severe form (with pneumonia), 12 per cent. Gallagher (1941) noted 11 cases of mild infection without pulmonary involvement that epidemiologically both preceded and followed cases of so-called pneumonia. Longcope (1940) has observed that patients may apparently contract a severe form of infection from those who have had a mild attack or that the reverse may occur.

During World War II, Dingle and others (1944) made a careful clinical, epidemiological, and etiological study of primary atypical pneumonia during a period of high prevalence at Camp Claiborne, Louisiana. Data regarding the manner of occurrence of this disease among the troops stationed at this camp were collected from February, 1941 to March, 1942. Cases were occurring throughout this period but the incidence rose to a sharp peak in July, 1942. The highest attack rate sustained by any organization was that for troops attached to the station hospital. Their rate was two or three times as high as that for any other organization. Among these troops, the attack rate for those whose duties brought them into contact with patients was seven times as high as for those who had casual or no contact with patients. With this exception, focal concentration of cases in companies and regiments was rare. Atypical pneumonia occurred in nearly every organization stationed at the camp during the epidemic and endemic period. In one division of troops, the observed distribution of cases of atypical pneumonia among companies was approximately the same as might be expected from a theoretical distribution if cases had occurred at random. Only rarely could one case of atypical pneumonia be traced to another.

The experiences which have been reviewed, together with others, support the hypothesis that the causative agent is at times widely distributed in human populations. In the great majority of individuals the infection is of mild form without serious pulmonary involvement and is classified as a common cold. In the occasional individual the infection is manifested in its severe form as primary atypical pneumonia. In some epidemics the virus appears to be more virulent than in others. There is little knowledge regarding predisposing factors, such as chilling, fatigue, or preceding upper respiratory illness. The duration of immunity following the illness is unknown. There is little doubt that the infection is transmitted from person to person by some form of association. Duration of the infectious period is unknown and the incubation period is thought to be seven to 21 days, and most commonly about 11 or 12.

**Prevention.** At the present time, no specific control measures are available. Isolation of cases seems indicated largely as a protection to the hospital personnel but cannot be considered as an effective means of control of the disease. Problems of preventing spread are similar to those of the common cold and other acute

respiratory diseases. The possibilities of air disinfection will be more fully discussed in a subsequent chapter. Evidence of active immunization is not available.

## INFLUENZA

The term "influenza" has had a popular and vague usage. It has been applied to common colds, acute catarrhal inflammation, brief febrile attacks of unknown origin, and even to gastro-intestinal disorders and nervous indispositions. When influenza sweeps over the world in pandemic form, it becomes the most serious and furious of epidemics on account of the large numbers attacked in a short time. There is a high incidence, with a comparatively low case fatality rate, but the mortality is high on account of the great number of cases. In the world-wide pandemic of 1918-1919, it is estimated that there were over 200,000,000 cases and that upwards of 10,000,000 deaths occurred in less than 12 months; in the United States alone there were more than 20,000,000 cases and about 450,000 deaths in less than six months. In India, 4,933,132 deaths from influenza were reported from June to November, 1918.

The early history of influenza is necessarily veiled in obscurity. Hirsch in his great work gives a summary of periods when influenza was pandemic. There is an account of an epidemic, probably influenza, recorded in 1173. Many outbreaks of "plague," some of them doubtless influenza, occurred long before this. The first authentic outbreak was described in 1510 by the famous physicians Willis and Sydenham. There have been about 80 epidemics, more or less authentic, since 1173. Fourteen pandemics have been recorded since 1510; they are those of 1510, 1557, 1580, 1593, 1729, 1732, 1762, 1788, 1830, 1833, 1836, 1847, 1889 and 1918—about four a century. The relation of sporadic and interepidemic outbreaks

to pandemics of influenza is not clear. Indeed the medical historian dealing with these epidemic phenomena can only surmise as to whether they are related or unrelated—whether they are of similar or dissimilar etiologies. Thus, up to recent years the practical definition of influenza (according to Major Greenwood) has amounted to this: "An apparently sudden disturbance of the public health by the occurrence of a very large number of cases of illness characterized as regards a majority by signs and symptoms affecting the respiratory tract."

Nonetheless, the clinical, pathological, and epidemiological descriptions have become increasingly representative and precise during the past half century. Rarely, if ever before, in the annals of medicine, has a manifestation of epidemic disease been studied by numerous observers with so much ardor and reported with so much fullness as was the pandemic, perhaps the greatest of all influenza epidemics, of 1918-1919 (Jordan, 1927). The interest created by this startling phenomenon continued through the succeeding decades, leading to the discovery of the influenza viruses and the development of laboratory procedures permitting an etiologic differentiation. Contributions since 1933 have gone a long way toward explaining the biologic process which is called epidemic influenza.

**Clinical Definition.** Many descriptions of the signs, symptoms and course of influenza in different epidemics, times and places have been written. In its ordinary manifestations influenza merges with the common cold, febrile catarrhs, and other acute minor respiratory infections discussed in the preceding sections (Stuart-Harris and others, 1938; Francis, 1939b; Commission on Acute Respiratory Diseases, 1948b). The common features are an abrupt onset with chills or chilliness, fever, headache, muscular pains, prostration, cough, and nasal symptoms. The fever lasts from one to six days, usually two to three. Convalescence is usually uneventful, although it may be characterized by a considerable degree of depression and fatigability. From this general pattern, the clinical picture of epidemic influenza varies both towards mildness and towards severity. In the more severe cases the evolution of the illness is more rapid and intense. The constitutional reaction is prominent from the beginning. Prostration is out of all proportion to the clinical symptoms. There is a rapid and extensive virus invasion of the mucous membranes of the lower respiratory tract, of the trachea, bronchi, and bronchioles. This results in destruction of ciliated epithelium over considerable areas. With the accumulation of mucus, desquamated epithelium and inflammatory exudate conditions are created which are favorable to secondary bacterial invasion. The extent and character of the invasion is very largely a matter of chance depending upon potential pathogens which happen to be present in the patient's throat. This in turn is determined by the type of bacterial throat flora characteristic of the community at the time. Thus, secondary pneumonias may be predominantly due to hemolytic streptococci, to pneumococci, to the influenza bacilli of Pfeiffer or to other organisms. In extremely severe cases death may occur within 48 hours.

The proportion of cases of influenza which are severe and complicated by pneumonia varies with each epidemic and with each locality during the same epidemic. The mortality is determined by the proportion of the population attacked and the frequency of this complication.

**Etiology.** The first break in establishing the etiology of influenza came with the report of Smith and others (1933) that they had isolated from the nasal washings

of influenza patients a strain of virus (W.S.) which was pathogenic for ferrets by intranasal route. Further, they found that the serum from recovered ferrets and from convalescent humans would neutralize the infecting capacity of this virus. The following year this work was confirmed by Francis (1937) who was successful in isolating a strain of virus (PR8) from a patient suffering from influenza in Puerto Rico. The work was taken up by other investigators and virus strains were isolated in many countries in several epidemics. Francis (1940) recovered a strain (Lee) from an institutional epidemic similar to, but immunologically distinct from, the strains which had been previously studied. Subsequently, strains of the original type like PR8 and W.S. have been designated as influenza A and the strains of the Lee type as influenza B. Extensive work in many laboratories has established the validity of these two types in the causation of influenza.

The physical, chemical, and biological properties of these two virus types have been extensively investigated. Their host range has been explored; their pathological and immunological properties have been studied in man and animals; useful laboratory procedures for rapid recovery and identification of the viruses and for the demonstration of specific antibodies have been developed (Burnet and Clark, 1942). Most of the strains which have been recovered are related to these two types, but may differ from the prototype strains to some degree in their immunologic characteristics. However, a strain of influenza virus (called 1233) antigenically distinct from types A and B has been identified by Taylor (1949) and confirmed by Francis (1950) with the suggestion that it be classified as Type C.

**Virus Isolation.** Several methods are available for attempting the isolation of influenza virus from throat washings. The specimens should be obtained during the early phase of the illness. Virus may still be present in the secretions after defervescence and not uncommonly up to the sixth day after onset, but rarely later.

**FERRET.** The original isolations of the virus of influenza A and B were accomplished by using the ferret; although the ferret is an extremely susceptible animal for detecting influenza virus and elaborate laboratory facilities are required for its care and handling.

**MOUSE.** In the early work, Andrewes, Laidlaw and Smith and Francis found that mice were susceptible by intranasal inoculation to ferret adapted strains. Neither ferrets nor mice could be infected by the subcutaneous or intraperitoneal routes. The mouse is less susceptible than the ferret upon original passage of human material. Nevertheless, it is possible to establish influenza virus from a patient's throat washings directly in mice without intermediate ferret inoculations. To establish the virus in the mouse as the primary host requires relatively longer series of intranasal passages at three- to four-day intervals and is slower than the other available procedures.

**CHICK EMBRYO.** W. Smith and F. M. Burnet in 1935 independently found the chick embryo was susceptible to infection with influenza viruses and showed that multiplication occurred in the chorio-allantoic membrane. This discovery afforded a method of studying the influenza viruses which was of inestimable value in advancing knowledge. For direct recovery of influenza virus from throat washings, inoculation of the hen's egg furnishes the simplest and most rapid method. Unfiltered throat washings to which chemotherapeutic agents (sulfonamides, penicillin, or

both) have been added give the highest proportion of successful recovery of the virus. While different routes of inoculation are used by individual investigators, the intra-amniotic route is the most sensitive (Hirst, 1948). Maximum virus titers are attained in the embryonic culture medium in about 48 hours in ten- to twelve-day-old embryos. Usually virus can be demonstrated in fluid from the first passage embryos but occasionally not until the second passage is carried out. Serial transfer through two to five egg passages may be necessary to increase the concentration sufficiently to produce the hemagglutinating effect. The hemagglutinating factor may be identified as the virus of influenza A or B or C with the aid of suitable antisera which specifically inhibit the agglutinating effect of the respective viruses.

Isolation of influenza virus from throat washings by any method is not a highly reliable method of determining the frequency of infection either in patients or in well individuals. If it be granted that an increase in serum antibodies indicates infection, then isolation of the agent was successful in approximately one half of the patients studied and in one eighth of well persons actually infected with the virus in the 1943 epidemic at Fort Bragg (Commission on Acute Respiratory Diseases, 1948a).

**Properties of the Virus.** Intranasal instillation of either type of virus leads to the development of the disease in man. However, subcutaneous or intramuscular injections of a fully active virus do not cause illness in human beings. Experimentally induced illness tends to be somewhat milder than the natural disease but in other respects does not differ significantly.

Influenza virus strains have been maintained in tissue culture for long periods. After more than 700 transfers a strain was found to have retained its pathogenicity for mice and ferrets (Francis, 1947). Infectivity is lost following heating to 56° C for a few minutes. These viruses are easily inactivated by irradiation with ultraviolet light, with formaldehyde, and numerous other reagents. The infectious titer of suspensions decreases in a few hours at room temperature but is little affected by storage at 4° C for a week. Purified preparations properly buffered may be held at 4° C for a month without showing any marked reduction in titer. Suspensions stored in sealed ampules at -76° C show no diminution in infectious titer.

Although highly purified by various procedures, it has not been possible to obtain influenza virus entirely free of extraneous material. On this account, knowledge of the chemical constitution of the virus, although it has been advanced, is not yet precise. However, many of the physical characteristics of the virus have been ascertained. As visualized under the electron microscope, these viruses appear as discrete particles of a relatively uniform size and shape. They are spherical, or nearly spherical, with diameters of 100 m $\mu$ . Both A and B virus strains cause so-called toxic reactions following intracerebral, intraperitoneal or intravenous injection in mice, guinea pigs, rats, and hamsters (Henle and Henle, 1946). The toxic property cannot be separated from the infective property, and is not the result of virus multiplication.

**Serological Diagnosis.** For the identification of influenza in animals and man, three serological procedures have been devised and developed. The principle involved is the demonstration of an increase in antibody titer for the viruses of influenza A or B or C by comparison of acute and convalescent sera. In all three the basic procedure involved is the same, i.e., the determination of the greatest dilution of

serum required to neutralize or inhibit the action of virus. Each test differs in the indicator employed.

1. **MOUSE NEUTRALIZATION TEST.** In this test the antibody content of a serum is estimated as the highest dilution that will prevent death within 10 days in mice inoculated with dilutions of serum to which has been added a standard number of lethal doses of virus (Francis and others, 1937). If the titer of the convalescent serum is four times or more higher than that of the acute it is evidence that the individual or the animal from whom the serum was obtained had had an infection due to the type of virus used in the test. While this test is dependable, it is laborious and time consuming.

2. **COMPLEMENT-FIXATION TEST.** The antibody content of a serum can be indicated by the degree to which the serum can be diluted and still fix complement in the presence of a standard quantity of influenza antigen (Friedewald, 1943). The antigen used is either virus grown in the fertile hen's egg or on an extract of the lungs of infected mice. When the complement-fixing titer of a convalescent serum is found to be fourfold or greater than the acute phase serum a diagnosis of influenza due to the type virus used in the test is warranted.

3. **THE AGGLUTINATION-INHIBITION TEST.** In 1941, Hirst observed that influenza viruses possess peculiar capacity to cause agglutination of red blood cells. Moreover, it was found that in the presence of antibody agglutination of erythrocytes by virus was inhibited. On the basis of these observations, a simple serologic method was developed (Hirst and Pickels, 1942). The antibody content of a serum is indicated by the highest dilution of serum that will neutralize or inhibit the agglutinating effect of a standard quantity of virus. An immune serum can be diluted to an extent proportional to its virus neutralization titer before its capacity to inhibit agglutination by a constant amount of virus is exceeded. The test thus measures either the level of neutralizing antibodies themselves or some other factor in the serum level which is closely parallel to such antibodies. This test is now used more extensively than any other.

**Human Susceptibility and Resistance.** Increased antibody may be demonstrated as early as seven days after the onset of illness. A maximum level is usually reached in two weeks, which persists for a few weeks longer and then begins to decline. After eight to 12 months the level drops to, or almost to, preinfection levels. New-born infants show sera with the same neutralizing activity as the mothers'. From six months to one year antibodies are usually completely absent; thereafter, the proportion of individuals with antibody shows an increase with age varying with local circumstances. The titer of antibodies in a serum is a reflection of experience of the individual with these influenza viruses in the recent and remote past.

As the virus has been recovered only from the respiratory tract and has not been detected in the blood stream at any stage of the infection, it has been generally considered that circulating antibodies, however measured, are not directly related to resistance to infection. Humoral antibodies, however, may indirectly determine resistance through the mechanism of nasal inactivating substances (Burnet and others, 1939; Francis and others, 1943). Little is known concerning nonspecific factors which may depress resistance temporarily. Thus, the titer of serum antibody is an indicator of susceptibility or resistance relative to virulence and dosage of the infecting virus strain and other factors. Practically, it has been found from observa-

tions on human beings both experimentally and naturally exposed that those with little circulating antibody are relatively susceptible and those with high titers relatively resistant to infection.

Studies by many investigators upon the distribution of antibody in the sera of persons during the course of an epidemic have demonstrated that a considerable proportion of infections are sub-clinical or inapparent symptomatically. For example, in an epidemic at Fort Bragg in 1943, hospital admissions comprised only half of the total of recognized cases of influenza A. Recognized febrile illnesses constituted only 21 per cent of the total infections as evidenced by increase in titer of antibody.

**Mode of Transmission.** The only known source of influenza A and B and C viruses is infected human beings. The infection may be expressed in clinical or inapparent form, the latter being much more frequent than the former. The virus is present in the respiratory secretions during the first few days of illness, rarely beyond the seventh day. Persistent carriers have not been demonstrated. As with other respiratory infections, transmission is effected during the acts of talking, coughing, or sneezing, and by secretions from the upper respiratory tract. The contagion may be passed from one individual to another by rather brief casual contact. Several investigators have demonstrated the possibility of air-borne infection for short distances under experimental conditions (Andrewes and Glover, 1941; Loosli and others, 1943). The relative importance of transfer by direct droplet spray, by air-borne droplet nuclei, and by indirect transfer by means of contaminated articles, dishes, and the like is unknown.

**Occurrence.** As its name implies, influenza is characteristically an epidemic disease. No part of the world is free from it for any long period of time. Every few years it occurs in widespread dissemination. These epidemics show a considerable variability in extent and duration. In a general way, reference may be made to those manifestations as pandemics, affecting large parts of the world as in 1918-1919 (Jordan, 1927); as waves affecting several countries and spreading internationally as with the B type virus in 1945-1946 (Andrewes, 1950); as minor waves limited very largely to a single country and its contiguous territory (Collins, 1930); and localized outbreaks affecting the smaller civil units only and sporadic groups of cases (Commission on Acute Respiratory Diseases, 1948b). Every gradation in prevalence occurs.

Because of the mildness of the disease and the lack of sharp clinical differentiation, official morbidity reports are notoriously unreliable as indices of prevalence. Over any long period of time and in any large geographic area what has happened can only be inferred from changes in mortality rates in respect to certain categories. Attention is concentrated upon deaths attributed to influenza and to pneumonia, since the two cannot be sharply distinguished. Figure 1-5, representing the excess annual death rates from influenza and pneumonia since 1917, reflects the experience of the United States (Collins, 1945). The peaks correlate very well with current medical reports of the occurrence of epidemics of influenza. The amount of excess corresponds roughly with the extent, duration, and intensity of the outbreak so far as it affected this country. Depending upon the extent of spread in a particular epidemic period, these peaks can be correlated to some extent with excess mortality from pneumonia and influenza occurring in other countries at about the same time. Outbreaks occurring in scattered localities, particularly when characterized by a low

frequency of pneumonic complications, would not produce the excess mortality necessary to become apparent in this figure. This limitation has become particularly evident in recent years with the lowered case fatality from pneumonia due perhaps in part to the use of antibiotics.

Fig. 1-5. Excess annual death rates: influenza and pneumonia by weeks: 90 cities, 1918-1943; 56 cities, 1944-1950.

After several years, during which there was apparently a low prevalence of influenza in this country, there were small epidemics in the winter of 1916-1917 and in April, 1918. These were followed by the pandemic, beginning in September and reaching a peak on October 16, 1918, with minor waves lasting until the spring of 1919. There was a considerable outbreak in the following year, 1920. Since that time there have been small outbreaks at irregular intervals up to the present. Virus A was identified in the cases occurring during the epidemics of 1933, 1935, 1937, 1939, 1941 and 1943. There is evidence to suggest that the epidemic of the winter of 1936 was due to virus B and this virus was isolated from cases occurring in the winter of 1940. On the basis of this formulation, the Commission on Acute Respiratory Diseases (1946) postulated that epidemics of influenza A had a periodicity of two to three years and epidemics of influenza B had a periodicity of four to six years. Following this postulation, an outbreak of B, reaching its peak in November and December, 1945, occurred as anticipated. A small outbreak of influenza A occurred in the spring of 1947 and again in the winter of 1949-1950. A longer

period of experience will be needed to assess the validity of this concept of a regular periodicity but it affords a useful hypothesis about which to assemble the facts known about the epidemiology of influenza in a meaningful pattern.

**Epidemiological Features.** Conditions are most favorable to the spread of influenza in the temperate zones during the winter and spring months. Nearly all epidemics reach their peak between November of one year and May of the next. A notable exception is the pandemic of 1918-1919 which began in September and reached its peak in October. Sporadic cases and small outbreaks may, however, occur during any month of the year.

All ages are susceptible to attack. The frequency of attack tends to be slightly higher in childhood but remains at a fairly constant level with a very slow decrease throughout adult life. The highest mortality rates are registered at the extremes of life. In general, case fatality is high under five, quite low throughout childhood and early life, rising rapidly in the older ages after 50. The pandemic of 1918-1919 showed two significant deviations from the general rule. It showed an unusually high incidence in young adult life with a rapid decrease after age 30. More strikingly, the force of mortality fell upon young and middle aged adults between the ages of 15 and 45 years. The important fact, however, is that influenza involves the whole life span. After the first few years of life there is no indication of the accumulation of immunity with advancing age. This is undoubtedly due to the fact that immunity following attack is of relatively short duration; the same individual may be repeatedly attacked after varying intervals of time.

Another characteristic is the rapidity with which influenza spreads. Large geographic areas become involved in a short period of time, so short indeed it seems almost as if there were simultaneous outbreaks in different places. Epidemics tend to be explosive in character. Duration in any one locality is from six to eight weeks. In compact communities, such as camps, an epidemic may run its course in four to six weeks. This rapidity of spread is explained by the short period of incubation, 24 to 72 hours, the large proportion of mild missed ambulatory infections, the relatively high proportion of the population susceptible to attack, and the ease with which the contagion is communicated from one individual to another.

Three factors are of particular importance in explaining the variation in intensity and extent of different epidemics. These factors are, respectively, the characteristics of the prevailing virus strain, the current state of susceptibility against this strain, and the amount of crowding and intercommunication in the affected population. With regard to the first factor, there are antigenic differences between strains recovered in different epidemics which have significant immunological implications (Friedewald, 1944; Gordon, 1942; Jordan and Gaylin, 1953). Types A and B are capable of considerable variation both in regard to antigenic structure and to biological properties of infectivity and virulence. Recovery from an attack from one strain of influenza, type A for example, does not completely protect against an attack from another strain of type A which is antigenically different. In regard to the second factor, the current status of susceptibility against the epidemic strain is indicated by low levels of antibody in the sera of the exposed population. The longer the time elapsed since the last experience with a given type, the greater the degree of susceptibility of the population. That such changes actually occur has been

demonstrated by several investigators. This is illustrated by the accompanying table taken from the study of influenza A at Fort Bragg in 1943, which shows a comparison of the pre- and postepidemic levels of antibody in the sera of 588 individuals. The third factor, i.e., the effect of crowding and intermixing among people

Table 1-4. Correlation between pre- and postepidemic titers of antibodies to influenza A

Pre-epidemic Titers	Postepidemic Titers								Total

has had repeated demonstrations. The highest attack rates from influenza are experienced in closed populations, such as in institutions, on board ships, among troops on board trains, and among troops quarantined in military barracks. On the contrary, among people living in rural areas with good housing conditions and relatively infrequent personal contacts the attack rate tends to be lower and the duration of the epidemic more protracted.

**Survival Between Epidemics.** The mechanisms responsible for the survival of influenza virus between epidemics has been a matter of speculation for many years. Two principal theories have been advanced. One is that influenza viruses have an existence in extrahuman reservoirs from which they emerge from time to time as conditions become favorable. This theory received support from Shope's interesting study of the mechanism of survival of swine influenza (Shope, 1941) which involved the lung worm and the symbiotic activities of *Hemophilus influenzae suis*. Although the virus of swine influenza is probably a variant or mutant of the human virus type A, the relationship between the swine disease and the human disease has not been established. No other extrahuman reservoir of type A, B or C influenza virus has been discovered. The second theory advanced is one of survival in the human host. According to this hypothesis, the influenza viruses propagate by continuous transfer from one human being to another, much as measles does between epidemics. If this were true, it should be possible to demonstrate sporadic cases in small outbreaks of influenza in nonepidemic periods. With this question in mind, the Commission on Acute Respiratory Diseases (1948b) conducted an intensive search for cases of influenza in the flow of a military population of a large Army post for a period of nearly three and one-half years. Serological examinations were made upon 2,932 patients admitted to the respiratory disease wards of the station hospital. During this period both influenza A and influenza B occurred sporadically as well as in epidemic form. Sporadic cases of influenza cannot be differentiated clinically

from cases of the common cold and other acute respiratory diseases. Sooner or later with the appearance of a new variant strain, with the accumulation of susceptibles in the population, or with the development of other favorable conditions the endemic prevalence is translated into an epidemic spread.

**Vaccination.** Early in the study of influenza viruses Francis and Magill showed that mice could be actively immunized against intranasal inoculation by means of subcutaneous or intraperitoneal injection of active mouse-lung or ferret-lung PR8 virus, thus establishing the principle that active resistance to experimental infection could be accomplished. The demonstration that influenza virus could be grown on the chorio-allantoic membrane of embryonated hen's eggs made available a practical method for production of large quantities of virus. Studies on vaccination of man against influenza were initiated in 1936, and pursued intensively by several investigators. Different preparations of both active and formalin-inactivated virus were employed. While these vaccines stimulated some rise in antibodies in vaccinated individuals, there was no acceptable evidence that they induced a sufficient degree of resistance to natural infection to warrant their use on a wide scale (Horsfall, 1940).

Francis (1939a) showed that within certain limits a direct proportional relationship existed between the concentration of virus used for immunization of mice and the degree of active immunity to intranasal infection induced. This suggested that a more concentrated vaccine than those being tried would be necessary to produce an effective immunity in man. Taking advantage of the observations of Hirst and others that influenza virus in the chorio-allantoic fluid of the infected chick embryo could be directly absorbed by the red blood cells of the embryo and that the absorbed virus can be readily eluted from these cells at 22° to 37° C, Francis and Salk in 1942 devised a simple procedure for producing a purified and more concentrated vaccine. By this method approximately tenfold concentrations of both PR8 and Lee strains were obtained consistently. This made possible the production of a potent mixed vaccine containing the PR8 and Weiss strains of A virus and the Lee strain of B virus which was suitable for large scale human trial to test the protective value under conditions of experimental and natural exposure. The results of these trials have been reviewed by Blake (1948).

In two adequately controlled experiments a considerable degree of success was obtained in vaccination against influenza A in the epidemic of November-December, 1943, and the influenza B epidemic in the fall of 1945. However, in another trial during the epidemic of influenza A in 1947, there appeared to be little or no protection of the vaccinated as compared to the unvaccinated groups. Subsequent studies showed that, while the vaccine produced antibodies against the PR8 and Weiss strains, it did not produce satisfactory level of antibodies against the 1947 epidemic strain, which received the designation "A prime." Each cubic centimeter of commercial vaccine available in 1952 contained Type A (PR8), Type A' (Cuppel, FMI) and Type B (Lee) strains. The adult immunizing dose is a single 1.0 cc. by subcutaneous or intramuscular injection. For children under 12 years, the dose should not exceed 0.5 cc., with proportionally less for the very young because of the apparently greater toxicity in this group. Persons sensitive to eggs, chicken or chicken feathers should not be vaccinated.

Salk (1953) obtained promising results experimentally by emulsifying influenza vaccine in mineral oil of low viscosity. The addition of this adjuvant increases the antibody response in titer and duration and gives broader antigenic coverage to include strains related but not identical to those in the vaccine. Many important practical questions require study and solution before an effective vaccine is at hand.

From the data available it would appear that a considerable degree of immunity would persist in the population group one year after vaccination. Annual repetition of vaccination would probably be required to maintain protection. It should be done prior to the appearance of an epidemic, because it requires at least a week to establish immunity and epidemics ordinarily spread so rapidly that it is impractical to undertake mass vaccination with the expectation that it can be carried through before the epidemic has reached its peak in any given community. Furthermore, the best method of vaccination and the best type of vaccine with respect to antigenic content, dosage, and method of injection remains to be determined. For these reasons vaccination against influenza must still be regarded as in the developmental stage.

**Control Measures.** The problems of preventing the spread of influenza are similar to those of other respiratory infections. The possibilities are considered in another chapter. On account of the widespread and rapid distribution of infections in a community, the large proportion of infections which are mild and ambulatory, and the fact that it is contagious in the earliest stages, measures of isolation and quarantine are of little value. In isolated population groups and in institutions infection has been delayed and sometimes avoided by strict exclusion of all visitors. During an epidemic it is advisable so far as is practical to urge voluntary reduction in activities which bring people into common assemblies. The attempt to prevent crowding by official regulations requiring the closing of schools, theaters and other places of public assembly is not advisable. Quarantine measures which interfere with the normal activities of a community are ineffective and not justifiable. The administration of influenza vaccine to large groups of people may be justified under some circumstances, but is subject to the limitations previously outlined.

During an epidemic the principal public health administrative effort should be directed toward providing good medical care to those who are ill enough to require it with a view to preventing complications and death. To minimize the severity of the disease and to reduce the risk of secondary infection persons becoming ill should be urged to go to bed at once and remain there during the febrile stage. Patients should have the advantage of appropriate chemotherapy if indicated for treatment of complicating bacterial pneumonia. On account of the risk of secondary infection hospitalization is to be avoided, particularly if crowded conditions exist and personnel and facilities are insufficient to care adequately for patients.

## PNEUMONIA AND PNEUMOCOCCAL INFECTION

The term "pneumonia" includes a group of varied diseases due to different causes, but all producing an inflammation in the lung tissue. Pneumonia may be primary or secondary; it may be lobar (croupous) in type or it may be lobular (bronchopneumonia); it may be due to bacteria, to fungi, to rickettsia, or to viruses. Classifications according to the anatomic pictures and the causative agents do not run parallel, but the latter are more significant from the standpoint of prevention and cure.

While the pneumococcus is the most common cause of pneumonia, pathogenic bacteria of other species and genera may be responsible, such as streptococci, Pfeiffer's bacilli, Friedländer's bacilli, plague bacilli, and typhoid bacilli. A pneumonic condition is also a frequent terminal state especially in the young and in the old. Because of the difficulties of classification, changing concepts of etiology and different standards of diagnosis, there is much confusion in the literature as well as in the morbidity and mortality records concerning pneumonia. A common error is to report death as due to pneumonia when the pneumonia is only a terminal event.

Lobar pneumonia is a clear-cut variety of the group clinically and histologically, and studies have shown that the pneumococcus is the responsible agent in about 95 per cent of the cases. This is an acute febrile infection with massive consolidation of lung tissue which, in typical cases, ends by crisis. The pneumococcus is found not only in the lungs and the respiratory tract but often invades the blood—an index of the severity of the infection. Pneumococci are also frequently found to be the cause of bronchopneumonias and secondary pneumonias complicating operations, trauma, and other conditions.

**Mortality from Pneumonia.** In 1900, pneumonia and influenza were the leading causes of death in the U. S. Registration Area. Death rates from these causes declined from 202 per 100,000 population to 38.2 in 1948. Referring to Figure 1-5, the decline was interrupted by epidemic rises associated with a series of epidemic waves of influenza, the greatest occurring from 1916 to 1920 associated with disturbances of World War I and the pandemic of 1918. With these exceptions, the general level of mortality from pneumonia and influenza remained about the same up to about 1937. Deaths from bronchopneumonia followed much the same trend, and deaths from lobar pneumonia had a similar configuration up to 1937. From that point on, interrupted only by the influenza outbreak in 1943, the decrease is more rapid for lobar than for bronchopneumonia. While this decline may be due in part to more accurate classification of deaths from specific causes, it would seem reasonable to suppose that the use of highly effective sulfonamides and antibiotics in specific treatment of pneumococcus pneumonias has been an extremely important factor (Chandler and others, 1949). The decrease in cases of lobar pneumonia

admitted to hospitals has been one of the most remarkable phenomena in the infectious disease pattern of the last few years.

**Typing of Pneumococcal Infections.** The fact that pneumococci can be classified into specific types which vary in their potential pathogenicity has been valuable not only in identifying the causative agent in cases of pneumonia but also in tracing the distribution of these organisms among persons suffering from subclinical or inapparent infection. A preliminary examination of suspected material, such as blood, sputum, pus, exudates in preparations stained by Gram's method, usually gives important information with regard to the nature of the infective agent. The ovoid or lancet-shaped cocci in pairs or in chains surrounded by capsular material affords a lead to identifying procedures. Growth is easily accomplished by means of nutrient broths or agar to which serum or defibrinated blood has been added. After 18 to 24 hours of incubation on blood agar plates, the colonies have a characteristic appearance. As in the case of other bacteria, the pneumococcus undergoes smooth to rough variation. The smooth colony type is characteristic of encapsulated type specific and fully virulent pneumococci. Rough colonies are associated with a loss of ability to produce capsules. The smooth to rough variation tends to occur in cultures maintained for long periods of time on artificial media. Reversal, rough to smooth variation, may be brought about by animal passage or cultivation of rough strains in the presence of antirough immune serum, heat-killed encapsulated cells, or extracts thereof.

Studies of the chemistry of the pneumococcus cell by Avery, Dochez, Heidelberg, MacLeod and others have contributed very greatly to an understanding of the fundamentals of immunology. The cell substance itself appears to be the same in all pneumococcus types. It is composed of proteins, nucleic acid, lipoidal materials and carbohydrates. The capsular material, known as a specific soluble substance (SSS), is a complex carbohydrate or polysaccharide. The immunologic differentiation of pneumococci into types is dependent upon the elaboration of SSS during growth. The production of these polysaccharides is essential to the pathogenicity of pneumococci and bears a direct relationship to virulence (MacLeod and Krauss, 1950). The antibodies which protect man and animals against infection neutralize the activity of this material.

Classification of the pneumococci into types began with the work of Neufeld and Handel in Germany in 1909 and 1910, who showed that there were definite serological differences between certain pneumococcal strains. Dochez and Gillespie (1913) were able by protection and agglutination tests to subdivide pneumococci into four groups: Type 1, Type 2, Type 3 and Group 4, or miscellaneous group. Cooper and her associates (1932) identified or reclassified 29 types which were previously considered together as Group 4. However, recent studies recognize a total of 75 antigenically different types. Certain of these types are much more important and much more widely distributed than are others.

The importance of mouse inoculation as a means of isolating pneumococci when present in small numbers, and particularly when mixed with other organisms of the common respiratory flora, is well recognized. Cultures can be typed by agglutinins or precipitin reactions with type-specific antisera. The Neufeld method of typing has also made possible the identification of pneumococcus types directly from sputum

or other infected materials and from cultures even when the organisms are present in relatively small numbers and in the presence of numerous other bacteria.

**Distribution of *Pneumococcus* Types.** The development of simple procedures for the typing of pneumococci led to studies by many investigators in various parts of the world of the frequency of different types in cases of lobar pneumonia and bronchopneumonia and in well persons associated with cases or in the general population (Heffron, 1939). From these studies, certain generalizations have been derived which are of value in understanding the occurrence of pneumonia in human populations.

Pneumococci are part of the constantly changing flora of the upper respiratory tract of man. The frequency with which various types are found varies with geography, season, age, sex, and other conditions. While all of the 75 or more types are potentially capable of causing infection, some of them are much more commonly associated with pathology than others. Type 1 and Type 2 organisms are intimately associated with primary lobar pneumonia and are found almost exclusively in relation to this disease. Type 3, although next in importance, is more widely distributed in normal throats and associated particularly with the pneumonia of old age. In the United States, these three types have been responsible for from 50 to 80 per cent of the cases of lobar pneumonia in adults, the remainder being due to Types 4, 5, 7, 8 and occasionally others. In the bronchopneumonia of adults the type distribution is similar to that found in well persons. In children below the age of 12, Types 14, 1, 6, 5, 7 and 19 have caused more than half the cases of pneumonia.

**Carriers.** The same specific type may persist and be recovered from the throat of a convalescent for only a few days or, in some cases, for several months; occasionally for more than two years. In some of the patients who remain carriers for a long time, pneumonia of the same type may recur.

About one half to one fourth of normal persons having no contact with pneumonia have been found to carry pneumococci at any given time. Webster and Hughes (1931) classified healthy individuals into four categories with respect to the finding of pneumococci in cultures from their nose and throat, namely, those who are free from pneumococci, the transients, the periodic and the permanent carriers. The same type or types may be found repeatedly in some persons, while in others they appear intermittently, and in still others different types appear and replace the earlier ones which are no longer found in subsequent cultures. Almost every person can be shown to carry pneumococci in the nasopharynx at one time or another if cultures are taken repeatedly. They are frequently recovered from infants after the first few months of life. Seasonal fluctuations in the incidence of pneumococci carriers correspond to fluctuations in the incidence of cases. Among family contacts of cases of pneumonia there is almost always a very high incidence of carriers of the same type of pneumococci that are found in the cases.

**Immunology.** Studies of the distribution of pneumococci in well persons have indicated that resistance against these organisms, both natural and acquired, is sufficient in most individuals most of the time to protect against clinical attacks. It has been estimated that ordinarily not more than one out of 500 persons harboring pneumococci in the course of a year develops pneumonia. One attack of pneumonia does not necessarily confer high or lasting immunity. Recurrence is more common

than in any other acute disease. The recurrence may be due to the same type or to different types.

Immunity is in part due to humoral antibodies and to a considerable degree type specific. The existence of this immunity can be demonstrated by various methods. Thus, fresh defibrinated blood of most humans has some bactericidal power against many types of pneumococci. This property may, in some individuals, vary qualitatively and quantitatively for different types of pneumococci. For each type, however, pneumococidal powers are present in the blood of infants during the first few days after birth with about the same frequency as in adults. Each infant resembles its mother in this respect. This pneumococidal power is apparently lost by the end of the first month and cannot be demonstrated again until after the first year. It is less frequent in children than in adults and declines again after 60 years of age. Blake (1932) found nontype-specific agglutinins in human serum. The curve of incidence of such agglutinins in the various age groups seemed to mirror the morbidity rates for pneumonia in the same community; that is, the morbidity was highest in the age groups in which the least agglutinins were found, and vice versa. Felton (1940) demonstrated mouse protection antibodies against one or more lethal doses of Types 1 and 2 pneumococci in the serum of almost one third of some 1,100 human subjects. Immediate positive skin reactions to type-specific polysaccharides (Francis, 1933) can be used to indicate the presence or absence of circulating antibody.

Studies made with these methods have indicated that the amount and types of circulating antibodies vary in individuals from time to time and from place to place. By analogy with other infections, it is reasonable to suppose that the pattern is determined by specific antigenic stimuli and experience with a pneumococcus infection, either clinically manifest or inapparent.

**Specific Serum Therapy.** Studies of the disease in experimental animals and man have led to the conclusion that if circulating antibodies are increased above a critical level, recovery from pneumonia usually follows. With a view to conferring passive immunity upon patients sick with the disease specific antisera were developed. Applied originally to treatment of pneumonia caused by Types 1 and 2, highly potent antisera later became available commercially for pneumonia caused by a majority of pneumococcal types. The early standard sera were prepared by the immunization of horses. Later, it was found that higher titers of antibody could be obtained by the use of rabbits. Dosage of antiserum was adjusted so that an excess of antibody was constantly present in the blood. As early as possible in the course of the disease serum was administered intravenously in an amount sufficient to result in a positive polysaccharide skin test. In most instances, defervescence and the onset of recovery occurred within a few hours after sufficient antibody had been given. Much was learned about the immunology of pneumonia from the use of specific serum therapy. However, in 1937, sulfa drugs were introduced and these, together with antibiotics, have proved to be so simple and effective in treatment that serum therapy has been given up.

**Nonspecific Factors in Resistance.** Before pneumococci can begin to multiply in lung tissue they must make effective contact with a cellular area in which conditions are favorable for growth. This involves passage through spaces in the upper respiratory tract of clumps of virulent pneumococci, usually in air-borne droplet nuclei or dust of particle size appropriate to reach the trachea, bronchi, or possibly

the terminal bronchioles. The first barrier in defense is the mucus secretion kept in motion by the ciliary action of the cells lining the respiratory mucous membranes and the associated reflex clearing mechanism. If this fails and pneumococci find lodgement in the lung tissues their immediate fate is determined by the numbers and

Fig. 1-6. Mortality rates per 100,000 population, United States, for pneumonia and influenza, lobar pneumonia and bronchopneumonia.

activity of the phagocytes in the neighborhood. From this point the humoral antibody begins to determine the issue. The total defense mechanism is only imperfectly understood, but evidently it is nicely balanced and easily disturbed by a number of conditions.

It is apparently less efficient in infants and old people and persons who are debilitated for various reasons. Pneumonia often closes the scene in chronic heart disease, pulmonary phthisis, Bright's disease, diabetes and other debilitating affections. Osler said: "Pneumonia may well be called the friend of the aged. Taken off by it in an acute, short, not often painful illness, the old escape those 'cold gradations of decay' that make the last stage of all so distressing."

Conditions favorable to the development of pneumococcus pneumonia result from the pathologic changes precipitated by influenza, measles, whooping cough, and other acute infections. Pneumonia may follow operations in which a general anesthetic has been administered, acute or chronic alcoholism, severe trauma, inhalation of irritant dusts and gases and, in general, conditions which may damage lung tissue and favor aspiration of micro-organisms.

While it seems likely that pneumococci of considerable virulence are essential to the production of pneumonia in lobar form, the evidence at hand also suggests that in the presence of such organisms the disease occurs in the usual instance as a result of temporary lowering of host resistance. Many investigators have called

attention to this matter and have stressed the importance of various factors, the most often mentioned are: acute minor respiratory infections, or other infectious diseases, exposure to temperature variations, chilling, wetting, and fatigue. Nevertheless, the fact remains that a considerable proportion of the cases of lobar pneumonia occur in healthy, robust individuals without apparent association with predisposing conditions.

**Mode of Transmission.** Spontaneous outbreaks of pneumococcal infections occasionally occur among animal stocks, particularly among guinea pigs and monkeys, when kept under artificial conditions. However, there is no reason to believe that there exists an extrahuman reservoir of any consequence. Pneumococci are primarily adapted to survival in the human race. The sources of pneumococcal infections are: cases, convalescents, and carriers, the last named being far more numerous than the others. As with other respiratory diseases, transmission from one individual to another is effected by means of talking, coughing, sneezing and contamination of articles or food by respiratory secretions. The relative importance of direct or indirect routes is unknown and probably varies with circumstances. The organism is comparatively frail, does not multiply in nature outside the body and is easily killed by sunlight and drying. It may survive for a period of time, usually a matter of hours, protected by mucoid secretions on contaminated objects and in floor dust. It is readily destroyed by heat; 52° C at 10 minutes is sufficient. On the other hand, it withstands low temperatures very well. The ordinary germicidal agents destroy it quickly and with certainty.

**Ordinary Occurrence.** Under ordinary circumstances, pneumococcus pneumonia occurs as a sporadic disease. The cases are scattered as to place, time, and persons. There is little tendency to focal concentration, although incidence bears a relation to density of population. In temperate zones, pneumonia shows a marked seasonal variation similar to that of the other respiratory diseases. Maximum prevalence is reached during the coldest months of the year. This is reasonably attributed to seasonal changes in the habits of living which bring people into closer contact indoors, thus favoring the exchange of respiratory micro-organisms. It is possible also that during these periods nonspecific factors depressing host resistance may be more generally operative than in the warmer months of the year. Otherwise, climate has no great influence on the distribution of pneumonia.

Inadequacies of reporting of pneumonia make it impossible to determine the exact incidence of the disease in persons of various age groups. Direct evidence concerning this matter comes frequently from the reports of hospitals and allied institutions, which at best give little more than an index of the relative frequency of pneumonia in any age group. It seems to be generally true, however, that pneumonia may occur at any period of life but the incidence is highest in the young and the old. Death rates both from lobar and bronchopneumonia are high under five years of age, relatively low throughout childhood and young adult life, increasing, at first gradually and then rapidly, with advancing years after 50. Most of the available data support the concept that pneumonia, and especially lobar pneumonia, is more frequent in males than in females. From many reports it appears that compared with white people living and working in the same district, Negroes have a higher morbidity and mortality rate for pneumonia. However, in these accounts it is not possible to discount differences in immunity acquired through previous experi-

ence of the racial groups. The frequency of pneumonia among African Negroes in the gold and diamond mines in the vicinity of Johannesburg, Pretoria, and Kimberley in the more temperate zones of South Africa, has been the subject of extensive investigation. The immunity of the natives appears to increase markedly after the elapse of a few months of time in the new environment. It seems probable that the unusual severity of pneumonia among the recent arrivals is due, not so much to fundamental differences in race, but to the fact that such natives had had little experience or exposure to the prevalent pneumococcus types and consequently have little initial effective resistance against these organisms. Marked overcrowding, usually associated with low economic status, undoubtedly favors the transmission of pneumococci and tends to increase the incidence of pneumonia. Persons engaged in certain occupations, especially those requiring fatiguing labor out of doors in all kinds of weather, those who experience intimate exposure to intense heat, and those exposed to some forms of dust have higher pneumonia morbidity and mortality rates, or both, than others not so employed. This also appears to be true in underground miners who may be exposed to considerable change in temperature during the course of their work and upon their return to the surface. The increased risk is not associated with the execution of the precise occupation so much as it is with the collateral conditions which may lower resistance to pneumococcal infection.

In summary, the principal factors controlling the prevalence of pneumonia under ordinary conditions seem to be (a) the nature of the infective organism, (b) the opportunity for acquiring the infection, (c) the nature of the predisposing factors to which the individual is exposed, and (d) the host and his resistance.

**Epidemic Occurrence.** There are many accounts of epidemics of pneumococcal pneumonia (Finland, 1942). These may be classified under two headings. The first is excessive prevalence of pneumococcal pneumonia in a population over a considerable period of time due to several types of pneumococci. Under the second are included sharp outbreaks which occur in inmates and personnel of hospitals for chronic mental diseases, in children's homes, orphanages and other institutions, in which a single type of pneumococcus is responsible for an unusual number of cases of pneumonia in a short period of time. A good example of the former is an epidemic of pneumococcal pneumonia which occurred among the personnel of an Army Air Force Technical Training School, over a two and one-half year period during World War II, investigated by Hodges and his colleagues (1946). In the population flowing through this station in that period of time there were 1,600 cases of pneumonia. *Pneumococcus* Type 2 was the predominant organism over the entire period, causing approximately 35 per cent of all cases of pneumonia. Types 1, 5, 7, 12 and 4 were responsible for large numbers of infections and were considered also as epidemic types.

From the data collected no simple explanation of the extremely high pneumonia rates encountered in the technical school could be offered. The high incidence appeared to have been the result of a number of factors. At the beginning of the epidemic, in the winter of 1942-1943, high carrier rates for the infective types were built up in the personnel of the school. Under conditions of crowding and dusty classrooms and barracks, and an unusual prevalence of undifferentiated respiratory disease, widespread transmission of these micro-organisms was facilitated. Propagation was maintained by the intermittent arrival and departure of classes in the train-

ing courses. There was a thorough mingling of the new relatively susceptible arrivals with the permanent party personnel and those held over from previous contingents. Among those who had their first experience with an infective type there were always a few who had an inadequate defense mechanism and came down with pneumonia.

Similar but less complicated situations are described in the reports dealing with outbreaks of single types (Strom, 1932; Smillie, 1936; Smillie and others, 1938; Gilman and Anderson, 1938; Stebbins and others, 1940). In these, it was more clearly evident that a highly virulent Type 1 or Type 2 pneumococcus had been introduced into a susceptible population under conditions which favored spread by carriers and person-to-person contact.

**Prophylactic Vaccine.** It has long been known that experimental animals may be rendered actively immune to pneumococcus infection by previous injection of nonlethal doses of pneumococci or even by the injection of dead cocci. Frequent attempts have been made to immunize man against pneumococcal pneumonia with various antigenic preparations within the past 35 years (Heffron, 1939). In the earlier trials the vaccines consisted of heat-killed pneumococci which were injected subcutaneously. Almost all investigators concluded that the procedure exerted a beneficial effect. The validity of these conclusions, however, can be questioned because of the variables which clouded interpretation, such as differences in the composition of the immunized group and control groups, uncertainty as to whether the specific pneumococcal types included in the immunizing preparation were the same as those currently causing pneumonia, failure to determine whether the observed decline in cases in the immunized group was due to a decrease in cases caused by pneumococcal types included in the vaccine, and inadequate control of the antigenicity of the preparation used. In more recent years preparations of capsular polysaccharides have been used following demonstration by Francis and Tillett in 1930 that the isolated polysaccharides are antigenic for man. Suggestive evidence was obtained, especially through the studies of Felton (Ekwurzel and others, 1938), that the immunization of man with capsular polysaccharides will prevent pneumococcal pneumonia. This evidence has been recently extended and more convincingly demonstrated by MacLeod and others (1945). In a carefully controlled human trial under military conditions they found that immunization of man with 0.03 to 0.06 mg. of each of the capsular polysaccharides of pneumococcus Types 1, 2, 5 and 7 given in a single subcutaneous injection was shown to be effective in preventing pneumonia caused by these types and not that due to heterologous types. The immunity appears within a period of two weeks following the injection of the polysaccharides. The duration has not been determined, although six months can be set as a minimum. The carrier rates of pneumococcus Types 1, 2, 5 and 7 were lowered significantly in the immunized group as compared to the controls. It was suggested that overall reduction in the incidence of carriers was responsible for the lowered rates in pneumococcal pneumonia in the nonimmunized group.

It has thus been demonstrated that under special conditions immunization with capsular polysaccharides can provide an artificial immunity of sufficient degree to decrease the carrier rate and lower the incidence of pneumonia. It is to be noted, however, that this can only be accomplished where the polysaccharides used in the vaccine are of the same type as the prevalent infecting organisms. With present knowledge it is not practical to produce a vaccine effective against all types. The

procedure, therefore, is still in the stage of experimental development, and applicable only to selected situations.

**Preventive Measures.** The prevention of pneumonia secondary to other acute infections and debilitating conditions is a matter of prevention and medical care directed toward the primary cause. The prevention of primary pneumococcal pneumonia should be considered both from the point of view of reducing morbidity and of reducing mortality. The problems associated with reducing the prevalence and spread of pneumococci in human populations is involved in the larger problem of control of respiratory disease in general which is considered in a separate chapter.

Precautions to prevent spread from a case of pneumonia to immediate contacts are in order. Isolation of the patients with aseptic nursing technic is desirable. Particular care should be taken in the disposal of discharges from the nose and throat of the patient, and handling of bedclothes, linens, blankets, and utensils contaminated therewith. Quarantine of familial contacts or close associates is not practical or justified. Upon the death or discharge of a patient thorough cleaning and airing of the room is sufficient, bearing in mind the danger from floor dust.

Occupational hazards created by working conditions, such as exposure to marked variations in temperature, wetting, chilling, irritating dusts, as well as the performing of strenuous, fatiguing labor out of doors in inclement weather, and other provoking factors can be reduced by appropriate attention to industrial hygiene.

To control outbreaks in dormitories, barracks, hospitals, asylums, labor compounds, prisons, and the like, procedures directed toward the discovery and isolation of carriers of the infective types of pneumococci are usually not practical. Under special conditions it may be worth while to search for dangerous chronic carriers (see material on streptococcus infections, page 80). Every effort should be made to reduce crowding in sleeping, living, recreational, and working quarters. Special attention should be given to housekeeping arrangements, removal of dust, and cleanliness of floors and surfaces. All cases of incipient respiratory disease with fever and constitutional symptoms should be promptly isolated in bed pending diagnosis. Appropriate chemotherapeutic or antibiotic treatment will shorten the period of infectivity and reduce the risk of spread of bacterial infection. It will, in like manner, reduce the risk of a fatal issue.

**Treatment.** Penicillin intramuscularly or oral penicillin G are usually effective in treatment. In the event of penicillin sensitivity or delayed response tetracycline antibiotics are substituted. Sulfonamide drugs and erythromycin are also effective.

## SCARLET FEVER AND HEMOLYTIC STREPTOCOCCAL INFECTIONS

In 1653, Sydenham differentiated the syndrome of scarlet fever, largely on the basis of the characteristics of the skin eruption, from measles and smallpox but this was not generally accepted until the middle of the eighteenth century. Because of the inflammatory process in the throat, which so often occurs in scarlatina, it was confused with *angina maligna* or diphtheritic sore throat until the French clinician Bretonneau pointed out the reasons for regarding diphtheria as a specific disease in 1826. It was well along toward the end of the nineteenth century, however, before these two diseases were distinguished in medical reports and statistics.

The syndrome of scarlet fever was recognized as acute infection, characterized by sudden onset, with fever, sore throat, and a rash followed by desquamation. The fever lasts about four days and declines by lysis. The rash is a generalized punctate erythema which usually appears within 48 hours, starting about the neck and spreading downward; the exanthem is visible on the mucous membrane of the palate and surrounding parts. The cheeks are flushed and the area about the mouth presents a dead-white pinched appearance (circumoral pallor) which is striking and characteristic. Vomiting often ushers in the disease and the strawberry tongue follows. The disease varies greatly in severity; mild and missed cases and carriers are common and spread the infection.

Clinically, either the toxic or the septic manifestations of scarlet fever predominate. The toxic type is characterized by prostration, fever, rash, and a red throat; the septic type, by tonsillitis, adenitis, sinusitis, otitis, and sometimes mastoiditis and septicemia. In a small proportion of cases evidence of nephritis appears about the third week. Occasionally rheumatic manifestations—arthritis and synovitis—develop during late convalescence.

**Trend of Scarlet Fever.** To Thomas Sydenham, "febris scarlatina" was a mild disease. By the end of the eighteenth century, a severe form was prevalent in England, for in Willan's reports on diseases in London in the years from 1796 to 1800, there are numerous references to the gravity of scarlet fever at that time. Immediately after this period the severity diminished. Bateman, writing of the disease in London in the years 1804 to 1816, frequently alludes to the mild type of scarlet fever. There is no question that a change occurred after 1830 and the disease became, as Creighton noted, "the leading cause of death among the infectious diseases of childhood." Apparently it remained so in England and in this country until the middle of the nineteenth century.

Pope in 1926, using Chapin's material, reviewed the experience of Providence, R. I., in regard to scarlet fever in the years from 1865 to 1924. The death rate of children of ages two to four had decreased in this interval from 691 to 28 per 100,000 (or to about one twenty-fifth of the rate of 70 years ago), but the attack rate had not presented a corresponding decrease. The decrease in the number of deaths could not be attributed to a lower average prevalence nor to any changes in the population, but must have been due to the lessened severity of the disease. From 1886 to 1888, one in every five cases died, while from 1923 to 1924, only one of every 114 cases ended fatally. Woods in 1933 showed that a similar change has occurred in England and Wales.

From Collins, S. D., Pub. Health Rep., 61:203, 1946.

Fig. 1-7. Trend of scarlet fever incidence, mortality, and case fatality in three states during 40 to 100 years ending in 1944 for deaths and 1945 (provisional) for cases.

The trend of scarlet fever incidence, mortality, and case fatality based upon official data from Massachusetts, Michigan, and New York is shown in Figure 1-7 (Collins, 1946). There was little change up to 1941 in the incidence of the disease as indicated by the rates based on reported cases. The case fatality rates continued to decrease up to 1937. This has been attributed to a change in virulence of the prevailing strains of the causative organisms, but perhaps to some extent indicates improvement in medical care. The accelerated decline which came in the late thirties coincides with the increased use of the sulfonamides and antibiotics in the treatment of scarlet fever and its complications.

These observations could be amplified and corroborated by a review of other reports, but the general facts are well established and appreciated. Although the decrease in case fatality rate has been more rapid in some areas than in others, perhaps more marked in southern than in northern climes, and more apparent during the endemic than during epidemic prevalence, it has become general throughout Europe and America. From a fearful and highly fatal malady, scarlet fever has become relatively mild and, in the vast majority of instances, an innocuous ailment.

**Pathogenesis of Scarlet Fever.** With the advent of the bacteriologic era it was confidently expected that the disease "scarlet fever" would be found to be due to a specific microbial incitant, just as were diphtheria, typhoid, tuberculosis, and other common infectious diseases. After 50 years of research, the true nature of the pathogenesis of the disease syndrome has finally become apparent.

The etiologic relationship of streptococci was suspected very early, but attempts to separate those types which were capable of causing scarlet fever from those which were not, by means of cultural and serologic procedure, were only partially successful. It became evident that they belonged to the "hemolytic" streptococci and that they possessed some degree of antigenic relationship. The nature of the essential biologic activity which distinguished them remained undiscovered until some 25 years ago.

At this time, as a result of the observation and experiments of Schultz and Charlton, Mair, Dochez, and the Dicks (1938), it appeared that the peculiar biologic activity which distinguished the hemolytic streptococci which caused scarlet fever was their ability to produce a particular toxin, called Dick toxin, or, more properly, erythrogenic toxin, erythrotoxin, or simply rash-producing toxin. It was demonstrated that the injection of bacteria-free filtrates of broth cultures of hemolytic streptococci containing this erythrogenic toxin into susceptible human beings reproduced cardinal symptoms of scarlet fever, except the sore throat; namely, fever, malaise, nausea, vomiting, and a generalized scarlet rash. This afforded a rational interpretation of the pathogenesis. The sore throat is due to the primary localization of a strain of hemolytic streptococci in the throat with the resulting inflammatory reaction. The characteristic constitutional reaction is due to the toxic products peculiar to these organisms. The complications and ultimate outcome are determined by the ability of the organism to proliferate locally and to invade the tissues progressively. Resistance and recovery depend upon the development of at least two types of immunity: (a) ability to prevent the growth and progressive invasion of the tissues, that is, "antibacterial immunity"; and (b) ability to neutralize the toxic products, especially the erythrogenic toxin, that is, "antitoxic immu-

nity." To what extent the latter affects the former is not yet clear. This conception of the pathogenesis of scarlet fever has now received general acceptance.

**Identification of Scarlet Fever Streptococci.** The question of the specificity of the scarlet fever streptococci is but a small part of the larger problem of the classification of streptococci in general and the correlation of types or subdivisions with the various conditions of health and disease in which they are found in man and animals. The status of knowledge was admirably reviewed by Sherman (1937). Attention here will be limited to those streptococci which produce characteristic beta-type hemolysis in blood agar.

The significant biologic activity which distinguished the hemolytic streptococci recovered from cases of scarlet fever was their ability to produce, under specified conditions of culture, the characteristic erythrogenic toxin. Effort was made to use this quality as a means of identification. It became evident, however, that the ability to produce erythrogenic toxin is a function not peculiar to strains of hemolytic streptococci from scarlet fever alone, but possessed not infrequently by non-scarlatinal strains. Neither on the basis of the quantity nor quality of erythrogenic toxin produced can a sharp distinction be made.

Researches upon the serologic identification of hemolytic streptococci, although discouraging for a long time, recently have been proved to be of considerable value. By means of a precipitin reaction, based upon the presence of these organisms of a group specific polysaccharide, the "C" substance, it was found (Lancefield, 1933) that the hemolytic streptococci could be divided into several broad *serologic groups* which correlated significantly with previous knowledge of host relationships and pathogenicity. In particular, nearly all of the strains of hemolytic streptococci which are important in human pathology, fall into one group: *Lancefield's Group A* (Swift, 1948).

Having established this broad group, it was possible to subdivide it into *types* by means of a precipitin test based upon extracts of the type-specific proteins, the "M" and "T" substances contained in streptococci, or by means of agglutination. Independently, Griffith (1934), by means of a slide agglutination, had established 27 types of "*Strep. pyogenes*" and stated that more than 30 such types exist. All but two or three of Griffith's types have been found to belong in Lancefield's Group A. There was thus afforded the basis for the serologic identification of the principal pathogenic hemolytic streptococci and their subdivision into types.

Certain types, 1, 2, 3, 4, 8, 10 (N. Y. 5), 11, 13, 15, 17, and 19 have been found fairly commonly in scarlet fever (Schwentker and others, 1943). It is equally notable that these same types, and those remaining, have been found in non-scarlatinal conditions, such as tonsillitis, septic sore throat, otitis, mastoiditis, septi-cemia, puerperal sepsis, erysipelas, as well as occasionally upon normal human skin and mucous membranes. In other words, *by serologic technic the types of hemolytic streptococci which cause scarlet fever can be identified, but they cannot, by this means alone, be differentiated sharply from the other types in Lancefield's Group A which have been recovered from nonscarlatinal conditions.*

**Erythrogenic Toxin and the Dick Reaction.** One of the most valuable contributions of the Dicks was the development of the skin test which bears their name. The Dick test consists of injecting a small quantity of erythrogenic toxin *into* the skin. The toxin is diluted so that 0.1 ml. contains just enough to produce the typical

reaction; this amount is also called a *skin test dose*. A positive reaction indicates susceptibility and a negative reaction immunity to scarlet fever. When positive, the redness appears in about six hours, reaches its height in 18 to 24 hours and subsides promptly. The reaction is a circular area of erythema, sometimes accompanied by edema and swelling of the skin of more than 10 mm. in diameter. In quite sensitive subjects, or with very potent toxins, the erythema may be from 20 to 30 mm. or more across. Most children with scarlet fever react positively to this test until about the sixth day of the disease, when they become negative. The Dick test, therefore, also has diagnostic significance. Infants under six months of age usually give negative Dick tests irrespective of the result of the test in the mother. Thereafter, children show an increasing susceptibility until about the fourth year when it is highest. With advancing age there is a gradual decrease in the proportion of susceptibles, which varies with time, place, and circumstances, until in adult life 70 to 80 per cent may react negatively. Experience has shown that anomalies occur as with other similar tests and certain limitations to interpretation which were not at first appreciated have become apparent.

Two important sources of error have been demonstrated: (a) the confusion caused by allergic reactions to other constituents of the test material containing nucleoprotein and other substances derived from the bacterial cell and growth products, and (b) qualitative differences in the erythrogenic toxin produced by some strains of streptococci.

Although there has been some difference of opinion as to the frequency of "pseudoreaction" due to allergy, and the necessity, therefore, for a simultaneous control test, recent work has emphasized that this source of error cannot be ignored, particularly in adults.

Concerning the second source of error, although the erythrogenic toxin produced by most strains of scarlet fever streptococci is essentially similar, some degree of heterogeneity exists (Coffey, 1938). To cover the range of variation, the Dicks required that the pooled products of four selected strains be used in the manufacture of toxin and antitoxin. The scarlet fever antitoxin in routine use produced under the Dick patents neutralizes the toxins used in the Dick test, but fails to neutralize the toxins of about 10 per cent of the strains isolated from patients in the United States. When exposure to such strains occurs, one might expect even a Dick-negative person to develop scarlet fever.

With these qualifications, *the Dick test is a reliable indication of the level of scarlet fever antitoxin* in the individual's tissues. A negative Dick test does not imply an ability to resist *infection* with hemolytic streptococci of Lancefield's Group A.

**Relation of Scarlet Fever to Streptococcal Sore Throat and Other Infections.** That scarlet fever streptococci might cause infections of the throat without a rash (*sine exanthematica*) had long been suspected and was definitely established by Stevens and Dochez in 1926. They observed that such infections occurred among persons who had negative Dick reactions, implying again that immunity against erythrogenic toxin does not necessarily imply protection against sore throat and its complications. Studies of the frequency of negative Dick reactions in relation to age and a history of attack have suggested that a considerable proportion of persons, perhaps four out of every five, gain their antitoxic immunity (Dick-negative re-

action) without having had recognizable clinical attack of fever with rash. Such observations would indicate that infections with hemolytic streptococci capable of causing scarlet fever, occur far more frequently without the rash than they do with it.

Some types of Group A beta hemolytic streptococci are incapable of producing enough erythrogenic toxin to cause a rash. These types are widely distributed and at times a not inconsiderable cause of nasopharyngitis and tonsillitis, with attendant complications. Such infections are of great importance as antecedents of rheumatic fever. Despite the absence of the identifying rash, the clinical findings alone will permit an almost certain diagnosis in some cases. Characteristically, such illnesses present the sudden onset of sore throat, pain on swallowing, fever and other constitutional reactions, diffuse redness and edema of the soft palate, tonsils and oropharynx, discrete or confluent exudate, enlarged or tender cervical lymph nodes. Confirmation of the diagnosis may be obtained by laboratory procedures. Many patients will have an elevated total leukocyte count, cultures of the pharynx will almost always show a predominant growth of beta hemolytic streptococci. Depending upon the availability and use of preceding criteria, a large percentage of streptococcal respiratory infections can be readily and rapidly diagnosed, particularly during an epidemic period. The term "septic sore throat" was formerly applied to the more severe manifestations of streptococcal sore throat, particularly when it was disseminated by milk.

In this connection a study by Stebbins and others (1937) of the records of 1,529 cases of streptococcal infection occurring in seven milk-borne epidemics in New York State during the period 1934 to 1936 is most interesting. Three of these epidemics were classified as scarlet fever and four as "septic sore throat." The clinical manifestations of cases observed in the various outbreaks were strikingly similar, with the exception of the presence or absence of a characteristic scarlet fever rash and desquamation. In the three epidemics classified as scarlet fever, a typical scarlet fever rash was observed in 60 per cent of the cases; 40 per cent had no rash. The character and frequency of complications were practically the same in the "septic sore throat" cases as in the scarlet fever cases. A previous history of scarlet fever had no influence on the frequency of infection with either clinical type of infection, but was associated with a lower incidence of rash in the scarlet fever cases. Dick tests done after recovery indicated that the proportion of persons who had become negative as a result of their illness was greater among those who had had scarlet fever than among those who had septic sore throat.

The implications of this study may be extended to other human infections with hemolytic streptococci of Group A, such as otitis, mastoiditis, puerperal sepsis, wounds and burns (Longcope, 1938). Whether or not the infection is accompanied by a *scarlet rash* will depend upon the balance between two factors: (a) the ability of the invading strain to produce a sufficient quantity of erythrogenic toxin under the conditions of growth in the tissues, and (b) the ability of the host to produce sufficient quantities of the specific antitoxin to neutralize this toxin. If the rash becomes manifest or if the case is associated with others which show a rash, it is classified as "scarlet fever." If no rash becomes apparent, it is an "infection with hemolytic streptococci." Whether the rash is of importance in prognosis or only in diagnosis is not yet clear, as the ultimate outcome of the infection depends upon the

ability of the organism progressively to invade the tissues. To what extent production of erythrogenic toxin facilitates this invasion is unknown.

**Public Health Implications.** From these considerations, it appears that neither from the point of view of specificity of the etiologic organisms nor from the point of view of clinical manifestations is scarlet fever a distinct disease. Just as the hemolytic streptococci which cause it merge into the other streptococci of Lancefield Group A, so the classical disease syndrome merges into those of related infection caused by this group. Accordingly, *scarlet fever should be regarded not as a disease entity but as a clinical manifestation of infection with one of the types of the Group A hemolytic streptococci.*

It follows logically that any program of prevention should deal with this whole group of infections and not simply with those which show a rash. The group includes (1) acute primary Group A streptococcal infections involving various parts of the upper and lower respiratory tract, from a simple nasopharyngitis to pneumonia with empyema, skin and wound infections, erysipelas, puerperal fever, and their suppurative complications; (2) late nonsuppurative complications, namely, acute nephritis, and rheumatic fever. There is a latent or quiescent period of variable duration, usually two to four weeks or more between the former and the latter manifestations.

**Modes of Transmission.** The ultimate source of all Group A hemolytic streptococci is infected human beings. The individual may be suffering from any one or any combination of the clinically recognizable infectious processes mentioned above or from a subclinical or inapparent infection or carrier state. The latter are by far the more numerous. The primary site of multiplication of this microparasite in the vast majority of instances is in the upper respiratory tract, the nose, sinuses, and throat. To the extent that they are present in the secretions of the nose and throat they are projected into the environment during the acts of coughing, sneezing, talking, spitting, nose-blowing. Hamburger and others (1946, 1949) have presented evidence that nasal carriers are more important than the throat carriers in spreading streptococci. The explanation resides in the fact that the nasal carrier contaminates his environment, including the air, to a far greater extent than does the throat carrier. Carriers whose sinuses are infected, or who have rhinitis, expel larger numbers of streptococci and for a longer period of time; they are the "dangerous" carriers. To the extent that streptococci are contained in the purulent discharges from wounds and infected tissues they make their way into the environment through contaminated bandages, dressings, sheets, pillow cases, bedclothes, and other articles. In dried particles of secretions or discharges they may remain viable in dust or on blankets, or on various contaminated surfaces for weeks or months.

Transfer from one individual to another may take place by rather direct conversational contact or by various routes indirectly. It may be by contaminated articles to hand, to food, to mouth; it may be by droplet nuclei and by dust particles for short distances through the air. This is discussed in detail in Chapter 2. Contamination of foods, particularly milk and milk products, occasionally gives rise to sharp outbreaks.

The conditions required for the transmission of scarlet fever are the same as for other Group A streptococcal infections except as modified by the requirements for the production of this particular clinical syndrome. New cases of scarlet fever arise as individuals are exposed to types of hemolytic streptococci which produce erythro-

genic toxin, and as these make effective contact with the tissues of individuals who are susceptible (Dick positive). In general, hemolytic streptococci from a case of scarlet fever are more likely to be of a type which can produce scarlet fever in the new host than are organisms coming from a case of sore throat without rash.

The period of incubation is usually three to four days; extremes are 12 hours and seven days. Infections of the respiratory tract are contagious from beginning of symptoms. The danger seems to be in direct proportion to the amount of discharge from the mucous membranes of the nose, throat, and adjacent passages and the number and virulence of streptococci contained therein. Most of the uncomplicated cases, even when not treated with antibiotics or chemotherapy, are no longer infectious after one or two weeks. The desquamating flakes of skin are not infective as was formerly thought. The organism frequently persists in the throat of convalescents for months and may lose its type-specificity. This may mean a loss of virulence, loss of capacity to spread, or both. In any event, "spread" as indicated by secondary cases decreases as time elapses from the onset of initial infection regardless of whether the organism is harbored in nose or throat (Dingle and others, 1953).

**Occurrence of Streptococcal Infections of the Respiratory Tract.** The frequency of various clinical manifestations or infections with these organisms vary within wide limits in different geographic areas and time periods. The morbidity and mortality statistics of *scarlet fever* are available from many countries and indicate the regional distribution of the types which produce this disease. The fact has long been recognized that scarlet fever is largely a disease of temperate zones and occurs but rarely in the tropics. It is interesting to note, for example, that although scarlet fever is rarely recognized in the vicinity of Rio de Janeiro, Brazil, children become Dick negative earlier in life than do children in New York City (Doull and others, 1927). Although the disease can occur in any month of the year, as the geographic location is more remote from the tropics, scarlet fever tends to show a more and more pronounced seasonal distribution. In the United States it reaches its greatest incidence from January to March; in London, over a period of 30 years, the mode of incidence fell in October and the minimum in April; in New Zealand, where the seasons are reversed, the greatest prevalence is from April to June and the lowest from November to February.

In large cities of the temperate regions scarlet fever is continuously endemic. In the smaller communities it may be absent for considerable periods of time and when introduced may prevail in an epidemic. The age distribution of scarlet fever cases closely parallels the age distribution of susceptibility as indicated by the Dick reaction (as seen in Fig. 1-8). One attack usually confers immunity for life but second attacks do occur in approximately 1 per cent of cases. Second attacks are presumably due to infection with a hemolytic streptococcus type producing an erythrogenic toxin with which the patient has had no previous experience. An individual may, however, have repeated infections with different types of Group A streptococci without rash. The "antibacterial" immunity to a particular type strain does not protect against the many other types to which the individual may be subsequently exposed.

The level of prevalence of *acute primary streptococcal infections of the respiratory tract* in any community at a given time is the result of past experience with, and the prevailing exposure to, different types of Group A hemolytic streptococci (Schwentker and others, 1943). At any given time the streptococcal flora of any

community includes a variable number of different types. The majority have practically no concurrent pathogenicity. A few are capable of causing streptococcal infections other than scarlet fever. Still fewer have the potential ability to cause scarlet fever and other streptococcal disease as well. What happens will depend in the first

From Schwentker, F. F., Janney, J. H., and Gordon, J. E., *Am. J. Hyg.*, 38:27, 1943.

Fig. 1-8. Age distribution of positive Dick reactions compared with the age distribution of cases of scarlet fever.

instance upon how favorable the conditions of living are for the rapid transmission of respiratory flora from one individual to another. This will be contingent in particular upon the degree of crowding in living, working and sleeping quarters, house-keeping cleanliness, personal hygiene, the presence of undifferentiated respiratory infections causing coughs and colds, and of predisposing infections such as measles and influenza. The second factor in the situation is the susceptibility status of the exposed population with reference to the prevailing types of Group A streptococci. This susceptibility refers primarily to what proportion of the population has acquired resistance to these particular types ("antibacterial" immunity), and secondarily to what proportion have acquired resistance to the particular erythrogenic toxins they elaborate (Dick negative). The third factor is the potential pathogenicity of the prevailing type strains. This capacity is related to those biological qualities which determine the ability of the organism to invade the tissue (virulence) and its capacity to produce erythrogenic toxin. In general, the population will be most susceptible to the types with which it has had little or no recent experience, i.e., newly introduced strains; these types then have the greatest potential ability to spread and build up a high carrier rate. As the carrier rate increases and decreases the incidence of the acute respiratory streptococcal diseases rises and falls. Thus, in any contact-trans-

mitted epidemic several types of Group A hemolytic streptococci may be found, but one type usually predominates both among carriers and among patients. The prevalent clinical pattern, that is, whether cases are largely scarlet fever, or are streptococcal nasopharyngitis, tonsillitis or septic sore throat, will be determined by the pathogenic potentiality of this type.

The manner in which streptococcal infections spread through different organizations and from one organization to another in the U. S. Navy during World War II, the importance of this cause of man-days lost, the factors determining distribution and frequency, and the measures taken to decrease incidence have been described in interesting detail by Coburn and Young (1949).

**Food-Borne Outbreaks.** Contaminated milk may occasionally give rise to widespread and spectacular outbreaks of scarlet fever and streptococcal sore throat. A classic example is an outbreak of septic sore throat in Baltimore, Maryland, investigated by Frost (1912). It was estimated that not less than 1,000, and perhaps as many as 3,000 cases, occurred in this outbreak, causing 30 or more deaths. Apparently the milk supply in question became infected prior to its receipt at the distributing plant and the infective agent survived the inadequate "flash" process of pasteurization employed at that time. In the 25-year period from 1917 to 1941 a total of 160 outbreaks of milk-borne disease were investigated by the New York State Department of Health (Dublin and others, 1943). Septic sore throat and scarlet fever outbreaks comprised 34 per cent of those studied and contributed 68.2 per cent of all the cases. They were exceeded in importance only by outbreaks of typhoid and paratyphoid fever. Between 1935 and 1942 nine outbreaks were investigated in which serologically typed streptococci were incriminated. In eight out of the nine outbreaks the mode of contamination of the milk was through infection of the cow's udder. The usual history is that the cow has suffered a teat injury followed by development of acute mastitis due to manipulation of the injured part by a person with a sore throat.

Ice cream is seldom mentioned in the literature as a vehicle for the transmission of scarlet fever, but Ramsey (1925) reports one such outbreak occurring in Flint, Michigan. One hundred and sixteen cases of scarlet fever were traced to consumption of a particular ice cream. The evidence indicated that the ice cream mix before freezing had been contaminated by the ice cream maker who had scarlet fever.

During World War II, a food-borne outbreak of tonsillitis and pharyngitis due to beta hemolytic streptococcus Type 5 was carefully investigated by the Commission on Acute Respiratory Diseases (1945) at Fort Bragg, North Carolina. The infection was probably acquired from contaminated creamed eggs served at breakfast. The median incubation period for primary cases was 38 hours. Among 228 exposed to risk, there were 86 cases and 9 carriers. The secondary attack rate among their contacts was 30.1 per cent, of whom approximately one-half were cases and one-half carriers.

**Artificial Immunization Against Scarlet Fever.** Following discovery of the role of erythrogenic toxin in the etiology of scarlet fever, the possibilities of conferring artificial immunity, both actively and passively, were explored. Treatment of patients by whole blood transfusion from immune donors was found to be a valuable therapeutic procedure in the more severe cases. Antitoxic horse serum was produced and used in treatment and for conferring temporary passive protection against scarlet

fever upon exposed susceptible contacts. The latter procedure is of questionable effectiveness and incurs the risk of serum sickness.

A method of active immunization was also developed and advocated. It required the repeated subcutaneous injection of erythrogenic toxin in graduated doses. Five subcutaneous injections of 500, 2,000, 8,000, 25,000 and 80,000 skin test doses of erythrogenic toxin, spaced at intervals of one week were recommended. Two weeks after the last immunizing dose the Dick test was performed and in 85 or more per cent of individuals reaction was changed from positive to negative. In practice, this method of active immunization was restricted almost entirely to nurses and internes and persons confined to institutions. There were practical objections to its use because of the large number of injections required and the frequency and relative severity of the reaction which followed one or more of these injections. Modifications have been proposed. There is evidence that active immunity thus produced protects the individual against the clinical syndrome of scarlet fever for some time. Evidence is less convincing that it protects against infections with Group A hemolytic streptococci without rash, and the attendant complications. Today in the United States there is little demand for active immunization against scarlet fever because of the current mildness of this disease and because it has been largely stripped of its terror by modern therapy.

**Control.** For similar reasons, and with better understanding of the epidemiology of streptococcal infections in general, our ideas of administrative measures instituted for the control of scarlet fever have been modified.

In English cities some half century ago, contagious disease hospitals were built on an extensive scale with the idea that hospitalization would control acute infectious disease. A number of cities hospitalized 95 per cent of the scarlet fever cases. Careful studies were made of the number of return cases coming to the hospital from families to which a scarlet fever patient had been discharged after varying periods of detention. For example, Leech in a study of 15,000 cases found that the percentage of return cases was 1.86 after an average period of 49 days or under; 1.12 per cent after an average period of 50 to 56 days; and 1 per cent when the isolation was extended 57 to 65 days. Despite these heroic and expensive measures of isolation, returned cases continued to occur. It is now accepted that this is inevitable. An occasional patient will continue to discharge hemolytic streptococci for weeks or months after recovery from acute illness. There is no convincing evidence that even in cities where hospitalization of scarlet fever patients was practically complete that this was a factor in decreasing the morbidity rate from this disease.

Up to a decade or two ago most large American cities required that cases of scarlet fever be isolated for a period of 28 to 30 days. Gradually, the futility of this procedure has been realized and more rational regulations adopted. It has been realized for some time that the isolation of frank clinical cases was relatively ineffective in preventing spread. This has become more evident as the disease has become milder in character and an increasing proportion of infections were missed and unreported or were not clinically identifiable. Moreover, there has been a growing realization that it is unreasonable to impose isolation measures on patients suffering from infection with Group A beta hemolytic streptococci simply because they had a scarlatina form rash and not to impose the same measures on patients suffering from infections with the same micro-organisms but without rash, whether the localization

of the respiratory tract or wounded tissues elsewhere in the body, whether the case required medical or surgical treatment, or both. Current practice emphasizes the desirability of the identification not only of cases of scarlet fever but of all infections with Group A beta hemolytic streptococci by adequate provision for clinical observation and bacteriological culture. Patients suspected of infection with Group A beta hemolytic streptococci should be isolated pending bacteriological diagnosis if laboratory facilities be available. They should be placed upon infectious precautions in a single room, a cubicle or a small ward, depending upon circumstances. The isolation period, whether in home or hospital, should be determined on the basis of clinical recovery but should not be less than seven days from onset. If the patient has received appropriate treatment with a chemotherapeutic or antibiotic agent, the period of communicability will have been shortened. In complicated cases isolation should be continued until discharges from suppurative lesions cease. Particular attention should be given to the so-called dangerous carrier—that is, the individual with a nasopharyngitis and sinusitis who is eliminating large numbers of streptococci in his secretions. To require that cultures of the nose and throat be negative for hemolytic streptococci before discharge is not practical. The organisms may be too few to be of significance or they may be nonpathogenic strains. At the termination of the isolation period, the room which the patient occupied should be thoroughly cleaned. Contaminated objects, floors and other horizontal surfaces, such as table tops and window sills, should be washed with soap and water. Blankets should be washed. Particular care should be taken that all dust and lint particles are removed from the room.

Restrictions upon familial contacts of a case should be imposed at the discretion of the attending physician in collaboration with local health authorities. Persons with symptoms of infection should be excluded from handling milk or other food subject to contamination. Under some circumstances it may be advisable to exclude all children in the household who have not previously had the disease from school for one week after the last possible exposure.

The prevention of excessive prevalence of scarlet fever and streptococcal diseases in schools, institutions, barracks, and similar groups is very largely a matter of avoiding overcrowding and of maintaining good housekeeping and personal cleanliness. Particular attention should be given to dust suppression (Coburn and Young, 1949). Repeated attempts to control the environment with ultraviolet light, germicidal mists and the oiling of floors and blankets have had little effect on the spread of hemolytic streptococci (Loosli and others, 1952).

Any group of cases of scarlet fever or streptococcal sore throat occurring in a short period of time should be investigated to ascertain whether or not there has been a common medium of dissemination through milk or other food. Whether schools should be closed during an outbreak varies with circumstances. In remote rural districts, where the children can be kept apart, this may be advisable, but in cities little can be gained. Better results can be obtained by daily inspection, by physician or nurse, of children for one week after exposure.

**Mass Chemoprophylaxis.** With the discovery of the effectiveness of the sulfonamides in the treatment of streptococcal infections, came the concept that the same drugs could be used to shorten and suppress the carrier state. During World War II

this was extended to the idea that the spread of hemolytic streptococci throughout a command of troops could be checked and reduced by the administration of adequate doses of the sulfonamide drugs to the entire personnel. This was tried by the U. S. Navy on an extensive scale. The experiment has been described in detail by Coburn and Young (1949). While drug prophylaxis was quite effective in temporary suppression of the carrier state and reduction in the carrier rate, certain distinct disadvantages became evident. The first was the risk of toxic effects of the drug itself to the occasional individual who was sensitive. The second objection was that mass prophylaxis led to the development of sulfonamide-resistant strains of hemolytic streptococci. These resistant strains could no longer be controlled either prophylactically or therapeutically by the drugs. In spite of these disadvantages there may be situations in smaller population units, such as schools and institutions, where it is possible under careful medical supervision to use chemoprophylaxis temporarily and briefly to reduce the carrier rate.

### ERYSIPELAS

References to a clinical syndrome designated as erysipelas appear in the earliest medical writings of antiquity. At one time it was known as St. Anthony's fire.

Hirsch defined it as "an infective inflammation-disease of the skin or one of the mucous membranes near to the external surface of the body (mouth, throat, vagina, etc.), which in all probability proceeds invariably from a solution of continuity or wound, and is characterized by its rapid extension over the surface, and by the infective fever that accompanies the local process; the latter in many cases is confined to the skin and in such cases mostly heals rapidly, leaving no permanent effects; but in other cases it extends to the subcutaneous tissue sometimes to even still more deeply situated parts, and leads to more or less considerable suppurations spreading along the surface." With the development of an effective general resistance, fever and toxic symptoms subside, local extension stops and recovery begins.

Although it still occurs sporadically, a century ago it was one of the most serious complications of wounds, whether inflicted traumatically or surgically. At times it prevailed in epidemics in lying-in and foundling hospitals, lunatic asylums, educational institutions, ships, and the like. Hirsch gives a chronological table of some 68 epidemics of malignant erysipelas which occurred in America from 1822 to 1881. He states that from 1841 onward the disease grew into a pandemic which did not cease until the beginning of the sixties. It is notable that only occasional, more isolated outbreaks were reported in the latter part of the nineteenth century. The decrease began before conscious precautions were instituted and before the disease was well understood.

In 1883 Fehleisen grew streptococci in pure culture from excised erysipelas lesions and produced the disease experimentally in human beings. Histological studies revealed that the inflammation involved mainly the superficial lymphatic vessels which were crammed with fibrin, leukocytes and chains of streptococci. There was also edema of the perilymphatic tissues. The peculiar evolution is due to the progressively diffuse lymphatic involvement. It seems probable that streptococci always gain entrance into the skin through some abrasion, although this initial site is not always demonstrable. It is now known that in nearly all instances some type

of Group A hemolytic streptococci is the cause of this clinical syndrome; rarely is it due to Group C streptococci.

With the introduction of surgical asepsis, erysipelas became more and more infrequent in occurrence until it was largely limited to debilitated infants and old people. The complete clinical picture is rarely seen today since adequate antibiotic therapy quickly arrests its progress.

#### PUERPERAL SEPSIS

(*Childbed Fever*)

It was long ago noticed that childbed fever was somehow associated with erysipelas, scarlet fever and with other infections. Notes regarding its contagious and epidemic character are found in the literature. Among these are the observations of Malouin at the Hôtel Dieu in 1746 and of Gordon at Aberdeen in 1795. Charles White of Manchester, England, in 1773 was a pioneer in antiseptic midwifery. On February 13, 1843, Oliver Wendell Holmes read his paper "On the Contagiousness of Puerperal Fever." He said: "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses." He presented evidence that the doctor who went from the autopsy table or from cases of erysipelas or sepsis carried the infection to women in childbirth. Semmelweis, in the Allgemeines Krankenhaus in Vienna, noticed a greater incidence of puerperal sepsis in the wards served by students, who often came from the autopsy room to attend deliveries, than in the ward used for instruction of midwives. Next, he noted at the autopsy of a friend dead of a dissecting wound the same pathology as that found in childbed fever. He immediately (1847) instituted disinfection of the hands with chlorinated lime and the mortality fell from 9.9 to 3.8 per cent, and to 1.3 per cent the following year. Both Holmes and Semmelweis met determined opposition. It was difficult for the physician to admit that he was the cause and carrier of fatal infection to his patients. Semmelweis was a martyr to his faith. He had a tragic end.

It was almost a half century later before laboratory evidence was produced which supported the concepts of these pioneer investigators. Bacteriological research led to improvement in obstetrical care which resulted in reduction of the death rate from puerperal fever from approximately 7 or 8 per 1,000 deliveries to less than a fraction of 1 per cent.

Following childbirth, the female genital tract inevitably presents wounded surfaces—endometrial areas from which the placenta has been stripped, cervical lacerations, and perineal tears. These wounded tissues become a *locus minoris resistentiæ* in which bacteria, particularly streptococci, easily proliferate. The source of the invading micro-organisms may be endogenous, since the normal vagina is often inhabited by many varieties of streptococci. However, they are usually introduced from exogenous sources. They may come from (1) the secretions of the patient's own nasopharynx; (2) from other patients having streptococcal diseases or wound infections; (3) from the nasopharynges of the attending physician or nurses; (4) from contaminated articles, instruments or clothing, or from the contaminated dust and lint in wards and operating rooms. If the puerperal fever is due to infection with Group A streptococci, serious and often fatal complications may

quickly ensues unless appropriate chemotherapy or antibiotic treatment is promptly instituted.

### EPIDEMIC NEPHRITIS

It has long been known that acute glomerulonephritis occurred as a late non-suppurative complication of scarlet fever. The incidence of this complication has decreased in the past several decades as the disease has become milder. More impressive is the fact that its frequency is extremely variable from year to year and in different epidemics. Occasionally, an unusually high incidence of acute nephritis has been recorded both in widespread epidemics and in focal outbreaks in small population units, associated with sore throat, with or without rash, and due to Group A hemolytic streptococci. A recent review of the literature (Rammelkamp and Weaver, 1953) suggests very strongly that the variations in the attack rate are determined by varying nephritogenic capacities of the infecting type and strain of microparasite. They have been associated particularly with type 4 or 12. Nephritic complications due to these types usually follow the acute streptococcal illness after a latent period of one to two weeks.

### RHEUMATIC FEVER

During the past century the concept of rheumatic fever as an entity slowly emerged from the joint diseases included under the vague term "rheumatism." Haygarth, in 1805, was the first to write a clinical monograph associating rheumatic fever with heart disease. Its infectious nature was suspected toward the end of the century. In 1904, Aschoff described what he believed to be specific histological lesions in the myocardium of individuals dying during the active stage of the disease. The Aschoff body came to be regarded by some as a specific reaction to an unknown specific etiological agent. Gradually the milder forms of this disease process were recognized.

It is now accepted that the most important manifestations are migratory polyarthritides, carditis, chorea, subcutaneous nodules, erythema marginatum. Of less diagnostic importance are fever, rapid pulse rate, nontraumatic epistaxis, abdominal and precordial pain, pallor, anorexia, weight loss, elevation of the erythrocyte sedimentation rate, leukocytosis, and electrocardiographic changes, chiefly the prolongation of the P-R interval. Any combination of these symptoms may occur. In its milder manifestations onset may be insidious and diagnosis difficult (Jones, 1944). Definite and even severe heart disease may develop in the absence of other clinical evidence. On the other hand, acute rheumatic attacks may develop quickly into a fulminating form and death may occur within a few days or weeks, or the course may be prolonged lasting months or even years with periods of activity interspersed with periods of quiescence. Characteristically the disease is very prone to recur, particularly during the first five or six years following the initial attack. Rheumatic fever is by all odds the commonest cause of heart disease in children and young adults.

**Occurrence.** For concepts of the frequency and distribution of rheumatic fever in various population groups recourse must be had to indirect sources of information and special studies. The use of mortality statistics is limited, because all too

often when patients with rheumatic heart disease die, they are labelled merely as having had heart disease without further qualifications as to etiology. The criteria employed in attributing a death from heart disease to the rheumatic fever process has varied with time and still has a wide variability in different areas of medical practice. Nevertheless, mortality from heart disease may be utilized as an index of the importance of rheumatic fever. Hedley (1937) found that for the city of Philadelphia, in 1936, the total mortality from rheumatic heart disease was about 25 to 30 per 100,000. Among infectious diseases this rate was exceeded as a cause of death only by tuberculosis, lobar pneumonia, and syphilis.

There are relatively few countries where compulsory reporting of rheumatic fever has been tried and where good results have been obtained; Norway, Denmark and Iceland were among the first. In these countries, estimates of the annual incidence of rheumatic fever fall in the range of about 1 to 2 per 1,000 population at all ages.

Most of the information regarding the distribution of rheumatic fever in different population groups has been obtained from special studies. These have been of several sorts: analyses of the experience of special rheumatic clinics and of hospital admissions, surveys to determine rheumatic fever prevalence among special groups such as school children, college students, recruits for the Army and Navy, industrial workers, or even of whole communities. Information from these various sources has been assembled and reviewed by Paul (1943) and by Wilson (1940). A few of the salient features may be mentioned.

Available evidence indicates that rheumatic carditis is prevalent and severe between the latitudes of  $50^{\circ}$  and  $40^{\circ}$  north, it diminishes in warmer climates, is almost unknown between the Tropics of Cancer and Capricorn, increases again as cooler climates are reached and is common between  $30^{\circ}$  and  $40^{\circ}$  south. There is also evidence that population groups living in certain limited geographic areas have a much higher mortality rate from this cause than others, as, for example, appears to be the case in a group of northwestern states, Montana, Wyoming, Colorado, Utah. There is a distinct seasonal variation in the incidence of rheumatic attacks. It is well established that in temperate climates both primary and recurrent attacks occur more frequently during the colder months of the year.

Rheumatic fever is rare in infants, but begins to occur in children about three years of age. Thereafter, its relative incidence steadily increases for seven or eight years, then drops during school age. But, although susceptibility to first and recurrent attacks declines rapidly in the years after puberty, rheumatic fever cannot be regarded clinically as a disease of childhood, for active rheumatic carditis and polyarthritis are common enough during adolescence and young adult life. First attacks may even be encountered in the fifth or sixth decades.

In a large number of studies the relationship between rheumatic fever and living conditions has been evident. The disease is acquired at a higher rate in cities than in rural areas and is more prevalent among people who are subjected to crowding within their homes. The urban prevalence of rheumatic fever is higher in the areas of lower economic status. There is general agreement that rheumatic fever tends to show familial aggregation. Wilson and Schweitzer have assembled evidence which

suggests that an underlying hereditary predisposition to rheumatic fever exists. It is difficult or impossible, however, to be sure that this apparent hereditary influence cannot be explained by common living conditions, environmental factors, and exposure.

**Relation with Beta Hemolytic Streptococcal Infections.** Association of rheumatic fever with sore throat was noted a great many years ago. As early as 1886 there were records of epidemics of rheumatic fever preceded by epidemics of tonsillitis. In more recent years it has become evident that the association was limited to tonsillitis caused by Group A beta hemolytic streptococcal infections. It is apparent not only in relation to initial attacks but holds as well for recurrences. Although not invariably demonstrable clinically and bacteriologically, failures may reasonably be attributed to brief mild, missed, or inapparent infections. Studies of the antibody content (antistreptolysin O) of patients' sera support this concept. Many of the epidemiological features of the two diseases are roughly parallel, particularly the geographic, seasonal, age, and socio-economic distributions. Atwater (1927) and Rosenau (1928) pointed out on the basis of mortality statistics that a "high year" for rheumatic fever was also a "high year" for streptococcal infections. The same opinion was reached on the basis of urban morbidity statistics on the two diseases; a ten-year study of annual fluctuations in prevalence within the city of New Haven, Connecticut, 1929-1938 (Farquhar and Paul, 1940) indicated that a "high year" for tonsillitis and erysipelas was likely to be also a "high year" for rheumatic fever.

Observations on smaller population units in schools, institutions, military and naval installations, made during the past 10 or 15 years, have uniformly come to the conclusion that epidemics of rheumatic fever in which the antecedents have been observed both clinically and bacteriologically, have been found either to follow or to have been associated in some way with the prevalence of hemolytic streptococcal infections. Madsen and Kalbak (1940) described a number of explosive epidemics of rheumatic fever which followed milk-borne epidemics of streptococcal sore throat.

During the past few years, post-tonsillitis barrack epidemics of rheumatic fever have been repeatedly observed. There is no doubt but what they may assume serious enough proportions in both the Army and Navy to represent a major problem in preventive military medicine (Coburn and Young, 1949). In the experience of the Armed Forces in the United States there was an average of 7,300 cases annually for the seven-year period 1942 through 1948. A conservative estimate of the cost of each case that occurs in the Armed Forces is \$16,000.

**Prevention by Therapy.** Attempts to prevent the occurrence or the recurrence of rheumatic fever during the past decade have centered around treatment of the streptococcal disease which precedes most cases of rheumatic fever. Coburn (1944), Kuttner and Reyersbach (1943) and Hodges (1944) showed that sulfonamide drugs given prophylactically not only reduced the incidence of streptococcal disease but also reduced the recurrence of rheumatic fever. This would seem to be a practical means of prevention in two situations: (a) closed groups in which the incidence of streptococcal disease is extremely high, and (b) in selected groups such as patients with inactive rheumatic fever or rheumatic heart disease where the danger of recurrence is great. This method of prevention has not proven to be practical for the general population, however, because of the toxicity of the sulfonamide drugs

and the high percentage of sulfonamide-resistant strains of streptococci that develop and the difficulty that is entailed in mass prophylaxis (Coburn and Young, 1949). Treatment after the development of the streptococcal infection with sulfonamide drugs has proved to be ineffective. The oral administration of penicillin also appears to be valuable in prophylaxis or recurrences (Kohn and others, 1950). Although penicillin, chlortetracycline, oxytetracycline and erythromycin are effective in alleviating the symptoms of acute streptococcal diseases, only penicillin and chlortetracycline therapy have been shown to reduce the incidence of rheumatic fever following such infections. Chamovitz and others (1954) recommended that penicillin be administered so that effective concentrations are maintained for at least ten days. This may be accomplished by a single intramuscular injection of 600,000 to 900,000 units of benzathine penicillin G or by the oral administration of 250,000 to 500,000 units of penicillin twice daily for ten days.

#### DIPHTHERIA

The occurrence of diphtheria can be traced back into the medical writings of antiquity. Most medical historians are agreed that the description given by Aretaeus the Cappadocian, in the second century, of the Egyptian or Syriac ulcer can be identified with some degree of certainty as diphtheria. He gave a clear account of a severe inflammatory disease of the throat, particularly in children, associated with the production of a whitish or discolored concretion which might extend into the mouth or descend into the windpipe causing dyspnoea or suffocation. Throughout the middle ages there are many references to a clinical syndrome of this kind and to epidemics of what was commonly called malignant angina. The first recognizable account of what was subsequently called "croup" was in the writings of Baillou (Ballonius) in 1576. In 1765, Francis Home of Edinburgh published his classical monograph entitled "An Enquiry into the nature, cause and cure of croup." He distinguished an inflammatory or catarrhal form less dangerous, and a purulent or membranous form very dangerous, which he regarded as different stages of the disease. The classical monograph of Pierre Bretonneau, the French clinician, often referred to as "Traité de la diphthérie," was published in 1826. By unsurpassed powers of clinical observation and generalizations based on accurate records and postmortem studies of a large number of cases, he formulated his doctrine of diphtherite (anglicized to diphtheritis) as a specific disease. The concept of croup was swept away or merged in that of diphtherite. Bretonneau argued for the specificity

of the peculiar exudate or membrane. The affected part is usually the throat, larynx, or trachea, but the disease may be on some other part such as a blistered surface of the skin, a cutaneous diphthérite.\* His differential diagnosis was based upon the pathological-anatomical characteristics of the disease process.

Although Bretonneau warned against confusing diphtheria with other diseases of the throat like it, those who came after him were inclined to diagnose everything as diphtheria which looked like diphtheria. There was some question as to whether scarlet fever and diphtheria were not identical, and difference of opinion as to the relation of croup to diphtheria. This confusion could not be resolved until the etiology was established and a bacteriological diagnosis and confirmation was possible. It was, therefore, well on to the end of the nineteenth century before diphtheria came to be distinctly differentiated from other infections of the nose and throat.

The knowledge of the etiological agent begins with the publication of Loeffler's report in 1884. Klebs had described the bacillus in the diphtheritic membrane in the previous year but had brought forth no convincing evidence of its causal relationship. In 1888, Roux and Yersin demonstrated the exotoxin and in 1890 Von Behring and Kitasato developed the antitoxin. Subsequent investigations have confirmed and extended the observations of these pioneers and today there is available a fairly detailed knowledge of the etiology, pathogenesis and epidemiology of diphtheria.

**The Disease.** Diphtheria is a specific infection due to the Klebs-Loeffler bacillus (*Corynebacterium diphtheriae*). It often begins insidiously without pain or local indications and with little or no fever. The disease may exist several days before it is noticed. Both from the standpoint of prevention and cure, early recognition is of prime importance. The period of incubation is from two to seven days, usually two.

The disease is characterized by a local fibrinous exudate, usually upon the mucous membrane of the throat, but it may affect other mucous membranes, the conjunctivae or wounds in any part of the body. The bacilli remain in the local lesion where they grow and multiply. There they produce a soluble poison, the diphtheria toxin, which is absorbed and causes the toxic symptoms. The serious nature of diphtheria may be due to the intense local inflammation, to the toxemia, or to complicating septic micro-organisms. The local inflammation is characterized by coagulation necrosis, fibrinous exudate and the formation of a grayish membrane. The process is due to the local irritating effect of the diphtheria bacillus and certain of its products, and is attended with congestion and edema. When in the larynx or trachea, death may result mechanically from suffocation. The local process is self-limited as a result of tissue reaction against the bacillus and its bacillary products, whereas the toxemia is neutralized with antitoxin.

The toxemia produces acute degenerative changes in the cells of various organs of the body. According to their extent and intensity these give rise to serious and sometimes fatal complications. The degenerative changes in the myocardium and the central nervous system are of particular importance. The former give rise to

\* In England, the word "diphtheria" was introduced by Farr in the Registrar General's report for 1858 on the ground that "the termination *itis* as in gastritis is used in medical language to designate pure inflammation of an organ which the root of the word expresses, hence *ia* has been substituted for *ite*, the French form of *itis*, as this cannot with any propriety be placed after *diphthera* designating a product of disease and not an organ of the body."

myocarditis. This occurs most frequently in the severe forms of the disease but may be found in cases which seem to be only mildly ill. In some instances, the presence of myocarditis can be determined only by careful examination. It may remain unsuspected until the sudden development of myocardial failure makes it evident. The signs of myocardial failure may first appear during convalescence and sudden death may occur several weeks after recovery. As a result of the degenerative changes in the central nervous system some form of paralysis occurs in from 10 to 20 per cent of cases of clinical diphtheria. Although the probability of its occurrence and its extent are usually related to the severity of the attack, it may occur after a mild attack, especially one that was unrecognized and therefore not treated with antitoxin. The muscles of the soft palate are usually the first and may be the only ones involved. Generally, however, other muscles are affected, especially those of accommodation, less frequently the extra-ocular muscles, the pharynx, diaphragm, and the muscles of the upper and lower extremities. In severe cases, on the fifth or sixth day there may be present signs of paralysis consisting of nasal voice and regurgitation of fluids through the nose. This, however, does not usually occur until the second week. The later it occurs the less likely the paralysis will be widespread. Knee jerks are frequently absent even when the process is very limited in extent.

Every gradation in severity and extent of complications is encountered. At one extreme there is a form which goes under the name of malignant diphtheria which is fatal early and is frequently associated with the presence of Group A beta hemolytic streptococci. In this form there is a marked swelling of the cervical glands and frequently extensive infiltration of the cellular tissue of the neck so that the head is thrown back to relieve pressure upon the larynx and trachea. The swelling sometimes forms a distinct collar, reaching from ear to ear, filling the whole space beneath the jaw ("bull neck"). By contrast, in some patients, the symptoms are no more severe than those of a simple sore throat.

Death in diphtheria may result from the toxemia, laryngeal stenosis, bronchopneumonia, late myocardial failure or respiratory paralysis. The case fatality rate varies with the virulence of the prevailing strains of *C. diphtheriae* in different outbreaks and in the same outbreak, with age and medical care. It is highest in the first two years of life. In diphtheria hospitals the mortality in children under two formerly varied from 60 to 80 per cent. The risk has been greatly reduced by modern methods of treatment.

**Diagnosis.** The diagnosis of diphtheria often rests upon a combination of clinical symptoms and laboratory findings. Positive cultures alone do not necessarily mean clinical diphtheria, even though sore throat and fever may be present. Cases of streptococcal tonsillitis, with follicular patches resembling false membrane, occur in diphtheria bacillus carriers. On the other hand, repeated negative cultures are significant in excluding diphtheria, provided the material is taken from the proper places and good technic is used. Diphtheria bacilli do not always lie on the surface and it is advisable to rub the membrane a bit roughly in taking specimens for cultures.

A presumptive diagnosis of a case suspected on clinical grounds can be made if typical *C. diphtheriae* are found in a stained film spread directly from a swab taken from the suspected lesion. However, the swab is rubbed customarily on a slant

of Loeffler's medium and the culture examined within 18 to 24 hours. The latter procedure is generally accepted as the standard technic, although the pleomorphism of the *C. diphtheriae* and the existence of the diphtheroids again interfere with the certainty of the findings. Isolation of the organism in pure culture employing a selective medium containing a bacteriostatic agent such as tellurite is the only certain method. With this technic the organism may, in addition, be tested for virulence. Many laboratories are employing a combination of the technics, inoculating a Loeffler's slant and later a tellurite plate. This provides for a rapid tentative diagnosis and permits further work with the organism in pure culture to determine whether it is a virulent or avirulent strain of *C. diphtheriae* (Am. Pub. Health Ass'n, 1950).

**Treatment.** Early recognition is extremely important, both for successful treatment of the clinical attack and for control of the spread of the infection. Always give antitoxin at once in a clinical case of diphtheria without waiting for bacteriological confirmation of the diagnosis. Time is the important element in the life-saving properties of antitoxin. The patient should be first tested for sensitivity to horse serum by intradermal injection. If there is no immediate reaction, 20,000 to 80,000 units of antitoxin should be given in a single dose, depending upon duration of symptoms and severity. Ordinarily the antitoxin is injected intramuscularly, but in severe cases part of the dose should be given intravenously. In addition penicillin may be administered, but it is not a substitute for antitoxin. Neither antitoxin nor penicillin can be relied upon to shorten the convalescent-stage carrier.

**Etiology.** The Klebs-Loeffler bacillus, *Corynebacterium diphtheriae*, is Gram positive, nonmotile, nonsporeforming, nonencapsulated and nonfilamentous. Occasionally slight branching forms and club-shaped cells are found. A feature which characterizes this organism, serving to differentiate it from some, but not all, of the related "diphtheroids," is the presence of the metachromatic granules which are demonstrated when the bacilli are stained with a suitable preparation of methylene blue.

The discovery of natural antitoxin in the circulating blood of horses employed for biological purposes prompted a fruitless search for an extrahuman host for *C. diphtheriae*. Other domestic animals, especially cats, dogs and fowl, have been suspected as sources of human infections, but evidence that there is any natural host species other than man is lacking. The cow was also considered, but it is reasonably certain now that this animal is not naturally infected, although pre-existing superficial lesions on the teats may be infected via the hands of milkers.

The diphtheria bacillus is, therefore, an obligate parasite of man. It has less resistance to adverse environmental conditions than do the majority of the spore-free bacteria. It is more readily destroyed by light, heat and disinfectants than is the typhoid bacillus, corresponding in this regard more to the frailer streptococci. The organism can resist drying for a long time when enclosed in the flakes of false membrane or protected in albuminous matter, and they may remain viable and virulent for some months under these circumstances. It is not killed by freezing but it is destroyed if held at 60° C for 20 minutes.

**Virulent and Avirulent Strains.** There exist nontoxigenic or avirulent strains of this organism that, while conforming to morphological and cultural attributes,

fail to form toxin in demonstrable quantities. The avirulent diphtheria bacilli do not produce toxin in demonstrable amounts, do not kill guinea pigs, and do not produce antitoxins. Toxigenicity, or virulence, is a stable strain characteristic; rarely is it lost. Freeman (1951) described the development of toxigenic strains of *C. diphtheriae* from cultures of avirulent *C. diphtheriae* as the result of the action of a specific bacteriophage. The occurrence of this phenomenon has been confirmed and defined more precisely by further studies (Frobisher and Parsons, 1953). Presumably, this change occasionally takes place in nature.

The most reliable test for toxin production or virulence is the classical method, consisting of the subcutaneous injection of 0.5 to 1.0 ml. of heavy saline suspension of a pure culture into a normal 250- to 300-gram guinea pig and into an antitoxin-protected control. Death of the unprotected animal or the appearance of a definite local lesion, and absence of any change in the control is accepted as evidence of virulence. The intracutaneous injection of pure cultures was introduced to conserve animals and has supplanted the original technic in most laboratories. Several suspensions may be injected in 0.1 ml. amounts into the shaved skin of the back of a rabbit or guinea pig. After four to seven hours, about 500 units of antitoxin are injected intravenously or intracardially and equal doses of the same suspensions are injected immediately afterwards at sites near the original ones. The toxin, if present, will cause a specific local inflammatory reaction with a superficial necrosis of the skin at the original sites of injection. The antitoxin prevents a lesion in the skin at the site of the control injections (Am. Pub. Health Ass'n, 1950).

An in vitro method of testing *C. diphtheriae* for virulence has been worked out by Elek (1948). With certain modifications it has been found by King and others (1950) to be a simpler, less expensive and more rapid method for determining virulence than any of the animal tests formerly used. This test is based upon the principle of toxin-antitoxin flocculation visible in an inoculated agar plate.

**Cultural Types of Diphtheria Bacilli.** Anderson and others (1931) proposed a classification of types of diphtheria bacilli on the basis of certain cultural characteristics. The differentiation was made (Am. Pub. Health Ass'n, 1950) on the basis of the appearance of colonies upon tellurite media, fermentation of glycogen, fermentation of starch, hemolysis from blood agar, growth in broth and morphology. Correlation appeared to exist between the severity of the course of the disease and the types of organisms recovered, which were consequently given the name of *gravis*, *mitis*, and *intermedius*. From further work it appeared that there are additional types not readily differentiated by the same criteria or occasional atypical and transitional forms. Frobisher and others (1945) described an additional type which was called *C. diphtheriae minimus* on account of the small size of the colonies on tellurite medium. Virulent and avirulent strains of all cultural types have been found to exist. Diphtheria toxin produced by all types is neutralized by the same antitoxin. Whether the terms "*gravis*" and "*mitis*" are wisely chosen or not is debatable. McLeod (1943) reviewed the evidence supporting the concept that *gravis* was associated with the more severe types of the disease. This has been questioned by other observers. The correlation between the type differentiation based upon these selected cultural characteristics and potential pathogenicity is not yet clearly established. Attempts to differentiate types immunologically on the basis of the antigenic composition of the

somatic substances of diphtheria bacilli, while showing differences, have not contributed a useful classification.

**Schick Test.** Early studies indicated that recovery from diphtheria depended upon the mobilization in the blood stream of sufficient amounts of antitoxin to neutralize the maximum quantities of the toxin liberated from the local area of infection with *C. diphtheriae*. In 1909, Römer, using a technic of titration on the skin of a guinea pig, fixed the level required for the protection of human beings against clinical attack at approximately 1/30 of a unit of antitoxin per milliliter of blood serum. Schick (1913) utilized this principle to develop a method by which a cutaneous test could be directly observed to determine whether or not an individual had circulating antitoxin in sufficient quantities for protection. The test depends upon the fact that diphtheria toxin exerts a local destructive or irritating action upon tissue. If at the point of injection there is a sufficient amount of antitoxin in the tissue fluids to neutralize the toxin, no injury occurs.

In practice, the test is made by the intracutaneous injection of diphtheria toxin so diluted that 1/50 mld. is contained in 0.1 ml. of a properly buffered diluent. Customarily the injection of this amount of toxic filtrate is made into the skin of the flexor surface of the forearm. As a control, a similar injection is made into the skin of the opposite forearm of the same material which has been heated to 60° for 15 minutes to inactivate the toxin. The control material, therefore, contains the broth elements in which the diphtheria bacillus was grown and the heat stable growth products of the organisms. Occasionally, a slight degree of edema appears around both injection sites within a few minutes but disappears very shortly. The injection areas should be examined at 48 hours and again at the end of from four to seven days. The following types of reaction can be distinguished.

The *positive* reaction consists of a circumscribed area of redness up to 3 cm. or somewhat more in diameter around the point of injection of the toxin. There may be some swelling and tenderness. There is usually a smaller central area, 1 to 1.5 cm. in diameter, dark red in color, which slowly disappears leaving in some instances a definite circumscribed scaly area of brownish pigmentation, which persists from three to six weeks. The area around the point of injection of the control material on the other arm remains completely negative throughout. A positive Schick test indicates that the individual has less than 0.01 unit of antitoxin per ml. of blood serum and, therefore, has an insufficient quantity in the tissues to afford immediate protection against clinical attack of the disease. Such individuals are commonly classified as "susceptibles." Actually, they are susceptible to infection, but not necessarily to clinical attack. If infected, they may produce antitoxin in such quantities and with such rapidity as to neutralize the toxin liberated by the invading micro-organisms before it can give rise to manifest clinical symptoms.

If the test is *negative*, both arms remain without reaction of any sort. Antitoxin is present in sufficient amount to afford protection to an ordinary exposure to diphtheria. A negative Schick reaction indicates that the individual has 0.01 of a unit of antitoxin per ml. of blood serum or more. Such individuals are, therefore, classified as "immunes."

A *pseudoreaction* indicates some degree of hypersensitiveness to the proteins contained in the toxic broth filtrate. About the point of injection of both the test

and the control material there appears an area of erythema in 6 to 18 hours which reaches its height in from 36 to 48 hours, and fades at both sites alike to disappear completely within three to four days. This should be interpreted as a negative (immune) reaction. Such an individual possesses sufficient antitoxin to afford protection but, in addition, is allergic to some component of the injected material.

In a *combined reaction*, a red area appears on both arms but differs in intensity and persistence. Around the point of injection of the toxin the reaction passes through successive stages of a positive test persisting five to seven days or more. Reaction on the control arm follows the course described for the allergic type of response and disappears on the third or fourth day. Since there is evidence of insufficient toxin to afford protection, this must be interpreted as a positive reaction indicating some degree of susceptibility. However, the existence of allergy is interpreted as suggestive of previous contact with the diphtheria bacillus or its products and as evidence of at least a potential state of immunity.

The allergic manifestations seen in a combined reaction or a pseudoreaction are rarely seen in infants and become more frequent in older children and adults.

**Primary and Secondary Antigenic Stimuli.** In his critical review of the Schick test and its applications, Dudley (1929) pointed out that in order to interpret the reaction in its relation to immunity it is absolutely essential to grasp the concept of primary and secondary stimuli.

In 1921 and 1922, Glenny and his colleagues published work which showed that when a dose of diphtheria toxin-antitoxin mixture is given to an animal, which has never been inoculated before, and which has no diphtheria antitoxin in its blood, there is a latent period of about three weeks before any antitoxin can be detected in the animal's blood. Antitoxin then appears, and its quantity gradually increases to reach a maximum about eight weeks after inoculation. The antitoxin titer then slowly declines. This is the type of response to a primary sensitizing dose in an animal with no previous experience of the antigen employed. If, after all or nearly all of the antitoxin has disappeared from the blood of an animal which has had such a primary stimulus, a second injection of toxin-antitoxin mixture is given, antitoxin reappears in three days instead of three weeks, and the antitoxin titer reaches its maximum in about eight days instead of weeks. Moreover, the quantity of antitoxin produced is 10 to 100 times the amount produced by the original primary stimulus. An antigenic inoculation which produces this type of response is termed a secondary stimulus. Thus, in an organism that has been sensitized by an antigen, although no antibody may be present in the blood, yet the animal, as regards its immunity, is in quite a different state to one which is not so sensitized. Such a sensitized or experienced animal may respond to further antigenic inoculations, or secondary stimuli, even if of very much smaller intensity than the primary stimulus, by making antibody at 10 times the rate and 10 times as potent as an inexperienced animal. Glenny and his collaborators have demonstrated that these two types of response to primary and secondary stimuli are probably of general occurrence, and take place with many of the specific antigen-antibody reactions in the animal organism. The conception of primary and secondary stimuli is of fundamental importance in understanding the phenomena of immunity to infectious disease. It is also of great practical importance in vaccine therapy, as Glenny's researches have explained the necessity of correctly spacing curative and prophylactic injections if the best results are to be

obtained. Glenny (1925) has summarized his own, and other workers' views, which no one interested in the subject can afford to miss reading. The primary and secondary stimuli concept explains the fact that nearly all observers of any experience report that the few relapses from Schick negative to positive, which have occurred after active immunization against diphtheria, with few exceptions, have responded immediately to a single dose of diphtheria antigen, even though the original immunity had taken much time and trouble to produce. The first course of prophylactic injections had acted as a primary stimulus enabling a much less intense second course to act as a secondary stimulus. O'Brien, in 1926, showed that even the minute dose of diphtheria toxin contained in the Schick injection is often sufficient to induce a rise in the antitoxin titer of the blood from below to above the theoretical threshold between positive and negative reactions.

**Susceptibility and Immunity.** Utilizing Römer's technic, it has been established that during the first few months of life the infant is protected if the mother has acquired immunity. Antitoxin is transmitted to the fetus through the placental circulation and to the infant in the mother's milk. The immunity which the infant may possess during the early months is gradually lost unless it is exposed to natural infection. At the end of the first year approximately 80 to 90 per cent of infants are susceptible.

Application of the Schick test to population groups has afforded an invaluable means of studying the manner in which antitoxic immunity is acquired with advancing age (Dudley, 1929). Figure 1-9 (Frost, 1928) shows the percentages of

From Frost, W. H., J. Prev. Med., 11:325, 1928.

Fig. 1-9. Percentages of children found naturally Schick-negative in New York City and Baltimore.

children found naturally Schick negative in New York City and in Baltimore about 1920, when relatively few had been artificially immunized against diphtheria. The rate at which this antitoxic immunity is acquired with advancing age varies widely. It is determined primarily by living conditions and the level of endemic or epidemic

prevalence of diphtheria in the community (Dudley, 1932). It is further modified by the extent to which the population is subjected to artificial immunization.

Under conditions of exposure in the United States, about one third of persons reaching young adult life remain positive. The results of a Schick survey among 18,000 Naval recruits, carried out during the period from October, 1941 to January, 1942 (Worcester and Cheever, 1949), indicates the manner in which immunity status varies in different parts of the country. Recruits from the South Atlantic and East and West South Central States had the lowest frequency of positives, 15, 13 and 16 per cent, respectively. The percentages of positive reactions in other regions varied from 39 per cent in the Middle Atlantic States to 50 per cent in the West North Central area. Similar results were obtained in an immunity survey of military recruits in the United States conducted in 1951 (Liao, 1954).

It is notable that a considerable proportion of individuals go through life without having developed a negative Schick reaction. This is explained in part by the fact that a considerable proportion of the individuals who have a positive test have experienced a primary stimulus. If exposed to infection, they are capable of responding with rapid production of antitoxin sufficient to prevent the development of clinical symptoms. Another possible explanation is, that the immunity to diphtheria depends in part upon a more fundamental phenomenon than the presence of antitoxin in the blood stream, namely, tissue reactivity or ability of tissue cells to localize quickly and hold invading bacilli near the initial focus of infection. The existence of such an antibacterial immunity as part of the human defensive mechanism has been indicated by several studies (Frobisher and Parsons, 1950).

**Carriers and Subclinical Infections.** Diphtheria bacilli do not necessarily disappear from the area of localized infection on the mucous membrane of the nose, throat or elsewhere with the establishment of convalescence. In about 50 per cent of cases they can no longer be recovered in culture when the local lesion has healed. On the mucous membrane of the nose and throat they may persist for some weeks, about 12 per cent of convalescents being positive at the end of two months, about 2 per cent at the end of three months, and approximately 1 per cent continue to be bacilli carriers for an indefinite period. The persistence of these micro-organisms in the nose and throat is favored by excessive adenoid tissue. Children whose tonsils and adenoids have been removed are distinctly less liable to diphtheria than those who have not had this operation performed and, in similar manner, they are less likely to harbor the organism for long periods of time. Nasal diphtheria is particularly liable to be associated with the carrier state. There may be a persistent serosanguinous discharge which contains large numbers of diphtheria bacilli. Convalescent nasal carriers are, therefore, an important source of contagion in the spread of the disease.

The concept of the role of mild unrecognized subclinical or inapparent infections in the spread of infectious disease was first developed by Koch during his studies of cholera in Hamburg in 1893. At about the same time, Park and Beebe examined throat cultures from 48 apparently well sisters and brothers of patients with diphtheria and found 24 of them were harboring virulent diphtheria bacilli. These observations were confirmed and extended by many investigators. Various estimates were made of the frequency with which virulent carriers could be found among familial contacts of cases of diphtheria. For example, in a carefully conducted study in Baltimore, from 1921 to 1925, it was concluded that approximately 23 per cent

of familial contacts were carriers of diphtheria bacilli. This rate varied from 31 per cent in the age group 0-9 to 20 per cent in the age group 20 and over (Kusama and Doull, 1931).

In a similar manner, carrier surveys were made upon institutional, school, military and civil population groups, particularly during the course of outbreaks of diphtheria. For example, Frost (1928) shows in Table 1-5 the result of bacteriological examinations of white children age 5 to 9 years, inclusive, in Baltimore

Table 1-5. Results of bacteriological examinations of white children aged 5 to 9 years, inclusive, in Baltimore schools in three surveys, 1921-1922

Period of Survey	Number Examined	Demonstrated Carriers of Virulent B. Diphtheria	
		Number	Per Cent
November to December, 1921 . . . . .	701	22	3.14
February to March, 1922 . . . . .	722	19	2.63
May, 1922 . . . . .	985	15	1.52
Totals	2,408	56	2.32

From Frost, W. H., J. Prev. Med., 2:325, 1928.

schools in three surveys, 1921 to 1922. At this time approximately 2.3 per cent of the school children were shown to be carriers of virulent *C. diphtheriae*. It should be noted that the percentages given in such surveys represent the proportion of individuals found positive at any particular time by the technical methods employed. The carrier rate in a population group is not static but constantly changing. New individuals are constantly being infected or reinfected and infected individuals are becoming negative. A carrier rate must, therefore, be interpreted in dynamic terms. If 1.0 per cent of a population are found to be positive at any one time, and if the average duration of the carrier state is about two weeks, perhaps 10 to 20 per cent of that population will have harbored the organism during the course of the year.

These direct observations as to the frequency of subclinical or inapparent infections with diphtheria bacilli were supported and extended by the results of Schick surveys. In the Baltimore studies reported by Frost (1928) and his colleagues whereas more than 68 per cent of persons had acquired immunity to diphtheria as indicated by a negative Schick test at the age of 15, only 12 per cent gave a history of having had an attack of this disease, a ratio of 5.7 to 1.0. Frost pointed out that only 21.5 per cent of children in this area were Schick negative on reaching the age of five years. On this basis, he calculated that the children had been immunized at the average rate of 4.3 per cent per annum in the first five years of life; by the end of the tenth year the proportion of Schick negatives was increased to 52 per cent, which corresponds to an average immunization rate of 6.1 per cent per annum between 5 and 10 years and, similarly, the rate per annum between 10 and 15 years is 3.2 per cent. He contrasted these rates with the official morbidity rate for clinical diphtheria between 1920 and 1923 in the same population. The results are shown in Table 1-6. For the whole age group under 15 the ratio of 6.6 immunizations to

Table 1-6. Mean annual rates of (a) specific immunization and (b) diphtheria morbidity, in three age groups of white population in study area in Baltimore

Age Groups	Mean Annual Rates per 10,000		Ratio a:b
	Immunizations as Indicated by Schick Tests (a)	Clinical Diphtheria (b)	
Under 5 years	430	96	4.5:1
5 to 10 years	610	86	7.1:1
10 to 15 years	320	21	15.2:1
0 to 14 years	453	69	6.6:1

From Frost, W. H., J. Prev. Med., 2:325, 1928.

one case of the disease agrees roughly with estimates previously made. From the progressive increase in the size of the ratio of immunizations to clinical diphtheria, Frost concluded that with increasing age children suffering infection with the diphtheria bacillus are progressively likely to develop immunity rather than the disease. From these and other data, which cannot be extensively reviewed, it has become apparent that the establishment of successive infections and resultant specific immunization in diphtheria takes place for the most part below the level of unaided clinical observation, i.e., subclinical or latent immunization. The exact ratio of subclinical to clinical infections differs in different geographic areas and from time to time in the same area, and even in different groups in the same area. It is determined by the circumstances of exposure, virulence of the prevailing strains and other factors.

**Transmission.** Since *C. diphtheriae* is an obligate parasite of the human host the ultimate source of all infections is a case of clinical diphtheria, a convalescent carrier or a subclinical infection. The organisms ordinarily leave the human host in discharges from the mouth and nose, occasionally from lesions at other sites. The modes of transmission follow the pattern of the upper respiratory group of diseases in general. Transfer from an infected to a noninfected individual may occur rather directly by droplets or by contamination of articles and hands to mouth. Since the organisms survive for hours or even days in the external environment, transmission may be indirect by contaminated articles or by dust. The relative importance of transmission by droplet nuclei and dust particles is unknown. Since the diphtheria bacillus grows in milk without appreciably changing its flavor or appearance this has been the occasional medium of dissemination for epidemic outbreaks (see Milk, Chapter 22).

**Artificial Active Immunization.** Park and Schroder (1932) were the first to realize that by using the Schick test to determine the susceptibility of children and a retest to note the changes in reaction it was possible to study the immunizing effect of various preparations and procedures. Early studies were concerned with the value of toxin-antitoxin mixtures for this purpose. The general principle involved in the use of these preparations was that antitoxic immunity could be conferred without

undesirable local and constitutional reaction by the injection of small doses of toxin which had been almost but not quite neutralized by the amount of antitoxin added. As a result of human trials with preparations containing varying quantities of toxin, agreement was reached upon the most favorable dose of toxin to be used and upon methods of standardization. It was found that three doses of the standardized toxin-antitoxin mixture of 0.5, 1.0, and 1.0 ml., spaced about three weeks apart, would change about 75 per cent of the injected individuals from Schick-positive into Schick-negative reactors.

At the same time, certain disadvantages in the use of the material became apparent. The antitoxin used in the mixtures was obtained from immunized horses. Although the horse protein injected is small in amount, about .001 of an ml. per dose, there is danger of inducing sensitization or of anaphylactic shock in the previously sensitive person. This objection led manufacturers to substitute an antitoxin prepared by immunizing goats and sheep. A more serious objection is, that the mixtures are somewhat unstable. They must be kept in the refrigerator while not actually being used. On the other hand, if frozen, they either lose their immunizing properties and become totally inert or they become toxic. The increased toxicity is sufficient to produce unpleasant general and local reactions and may react unfavorably upon a campaign for diphtheria prevention. For these reasons, the use of toxin-antitoxin mixture has been largely given up. It is occasionally employed in older individuals who may be extremely sensitive to the amount of protein contained in toxoid.

*Diphtheria toxoid* was first used in immunizing human beings by Ramon of the Pasteur Institute in 1923. Ramon (1924, 1925) named his product "anatoxine" but English speaking countries have adopted the name "toxoid" to avoid confusion with antitoxin. *Fluid toxoid* or *formol toxoid* consists essentially of a filtrate of a toxic broth culture of diphtheria bacilli to which has been added from 0.3 to 0.5 per cent formalin, followed by incubation at 37° C until toxicity has practically disappeared. The antigenic constituents of the broth filtrate, beside the toxin or toxoid, are the proteins derived from the meat and peptone used in the broth (unless a synthetic medium is used) and the proteins derived from the diphtheria bacilli. It contains no serum of any kind and can, therefore, be given without fear of sensitizing to later therapeutic dose of serum. Toxoid is very stable; the expiration date is 18 months from the date of manufacture. Freezing does not seem to change it, and no physical or chemical treatment yet applied has succeeded in restoring any degree of toxicity. It is usually administered in three doses, 0.5 ml., 1.0 ml., and 1.0 ml., at intervals of three weeks. In more than 90 per cent of individuals this will convert a Schick-positive into a Schick-negative reaction.

Soon after toxoid was introduced into use it was discovered that its antigenicity could be increased by precipitation with alum potassium in a final concentration of 1.5 to 2 per cent. The resultant precipitate is twice washed and resuspended in a volume of saline such that the final product has a quantity of the antigen specified in standardization. Thus, a certain amount of the inert and perhaps objectionable material included in toxoid has been eliminated. This preparation, known as *alum-precipitated toxoid*, is usually given in two doses of 1.0 ml. each, spaced three weeks apart. The immunizing effect is approximately equivalent to that of three doses of

fluid toxoid, changing a positive to a negative Schick reaction in more than 90 per cent.

In children up to 7 or 10 years of age severe local and general reactions following the injection of fluid or alum-precipitated toxoid are infrequent; in older children and adults this risk is increased. In a recent study Pappenheimer and others (1950) reported that the administration of fluid or alum-precipitated toxoid to an adult population was attended with a significant number of untoward reactions, some of which can be remarkably severe, as has been observed in the U. S. Army, and frequently elsewhere. Disability rates from such inoculations may run as high as 15 per cent. They found that nearly all of the severe systemic and local reactions occurred in Schick-negative individuals. There was a close correlation between intradermal reactions to the Schick control (pseudoreactions) and local or systemic reactions to subcutaneous injection of toxoid. In the groups that received purified material there was a significant reduction in the total number of such reactions.

All grades of reactions are seen, from local swelling and tenderness to severe illness with high fever and complete incapacitation lasting for two or three days. Pappenheimer and Lawrence (1948) showed that human subjects may be separately sensitive to either toxoid or bacterial protein or to both. Accordingly, it is good practice to do a preliminary skin test. This test may be carried out alone or as a control for the Schick test. One-tenth milliliter of toxoid diluted 1:10 or 1:20 is inoculated intracutaneously (Moloney test). A local area of redness at the site of the inoculation of more than 1 cm. in diameter disappearing within three days is interpreted as a positive reaction and indicates that the individual may give a local or general reaction to toxoid. These sensitive persons may receive toxoid in smaller doses, the first dose ranging from 0.2 to 0.5 ml. in 1:20 dilution depending upon the degree of reaction to the intracutaneous test. Subsequent doses may be given at intervals of two weeks and may be doubled if the local reaction from the preceding dose was not more than 3 cm. in diameter.

It has been found that diphtheria toxoid can be combined with other antigens to advantage (Volk, 1949). For example, Bell (1948) reported that the use of a mixture of alum-precipitated diphtheria toxoid and pertussis vaccine, given to young children in two doses, with a four-week interval, resulted in better protection against diphtheria as measured by the Schick test than that which would result from the similar use of ordinary unmixed alum-precipitated diphtheria toxoid. The combination of diphtheria toxoid, tetanus toxoid and pertussis vaccine has also been found to be effective (McComb and Trafton, 1950).

**Artificial Passive Immunization.** Before a satisfactory method of active immunization had been developed, prophylactic passive immunization was commonly used to confer temporary protection on exposed individuals. The usual prophylactic dose of diphtheria antitoxin is 1,000 to 1,500 units for an adult and 750 to 1,000 units for children. Schick recommended 50 units per kilogram of body weight. The protection thus afforded cannot be depended upon for more than two to three weeks. The advantage of passive immunity is that it is prompt. The disadvantage is that it lasts a brief time and produces a serum reaction. Death from anaphylaxis has occasionally occurred from its use. Doull and Sandidge (1924) estimated the risk to be of the order of one death among 75,000 persons receiving antitoxin. The adminis-

tration of diphtheria antitoxin prophylactically still has a place in selected situations, particularly in family practice.

**Active Immunization in the Presence of Antitoxin.** It has long been recognized that the passive transfer of maternal immunity to the newborn infant interfered to some extent with neonatal active immunization up to the time that antitoxic immunity was lost, toward the end of the first half year of life. Cooke (1948) brought evidence to confirm this concept by administration of combined diphtheria and tetanus toxoid to 284 infants, demonstrating a good response to diphtheria toxoid in infants lacking maternally transferred antibodies to diphtheria, and relatively poor response in young infants inheriting passive immunity. These results suggest that dependence cannot be placed on neonatal immunization of infants against diphtheria. However, the use of an antigen potentiated by an admixture with adjuvants or combined with other antigens, such as pertussis bacilli, may overcome the handicap. Bell (1948) found that 201 infants from two to five months of age who received alum-precipitated toxoid combined with pertussis vaccine showed essentially the same Schick negative rate a year later, as was found in 236 older infants given alum-precipitated toxoid alone.

These results suggest that in presumably susceptible children up to the third or fourth year of life, who have been exposed to infection, it may be desirable to employ both active and passive immunization. The administration of a prophylactic dose of antitoxin may be followed about a week later by the injection of a dose of fluid or alum-precipitated toxoid. Simultaneous active and passive immunization for the protection of infants and young children has been advocated by a number of observers. Phair and Root (1942), on the basis of animal experiments, concluded that the simultaneous administration of a prophylactic dose of antitoxin and an immunizing injection of alum-precipitated toxoid, under appropriate conditions, was justified in prevention of diphtheria in such susceptible contacts of known cases.

**Prevalence.** In the first half of the nineteenth century, diphtheria was endemic in Europe and the United States, apparently also in many other countries. From 1800 to 1850 more or less localized epidemics of malignant diphtheria were occurring from time to time, especially in France. Between 1850 and 1860 there developed, apparently from a focus in France, a great pandemic, within a decade spreading over the world. In Western Europe and the United States, the regions for which we have the best records, diphtheria became much more prevalent and much more malignant, insomuch that practitioners of the day often spoke of it as a "new" disease. Its mortality rose to extraordinary heights, which with considerable fluctuations was sustained for 25 to 30 years, i.e., until about 1885 or later when a consistent decline began.

The data in Figure 1-10 showing the case fatality, morbidity and mortality rates from diphtheria, in three states during 40 to 100 years, is representative of the general trend in the United States. The downward trend in the death rate began before antitoxin came into general use, which was about the turn of the century. A considerable part of the decrease in the case fatality rate which is apparent between 1900 and 1920 can be attributed to the use of antitoxin and better medical care. During this same period there was little if any decrease in morbidity from diphtheria as indicated by the rate based on reported cases. There is much evidence

Fig. 1-10. Trend of diphtheria incidence, mortality and case fatality in three states during 40 to 100 years ending in 1944 for deaths and 1945 (provisional) for cases.

to indicate that the abrupt drop in morbidity which began about 1928 was related to the increasing and widespread use of active immunization.

The same downward trend that was observed in North America up to 1925 was noted in many European countries. In some of these countries it was sustained up to the outbreak of World War II. However, in other countries, as in England and Wales and Scotland, it levelled off after World War I and in Germany it began to rise during the middle thirties. Shortly after the outbreak of World War II, an epidemic wave swept over most of Europe, affecting those countries particularly in which very little active immunization had been practiced. Manifestations of this recent pandemic of diphtheria have been described by Stowman (1946). In the United States this wave was apparently reflected by interruption in the previous rate of decline and a slight rise in incidence in 1944 and 1945, due principally to marked increases in the south and southwestern states. Since that time the decline has been resumed. The incidence of the disease has been reduced to the vanishing point in the northern states (Anderson, 1947), but the disease still persists in the rural south.

One of the characteristics of the recent pandemic of diphtheria has been marked increase in the proportion or, indeed, often in actual numbers of adult cases. This shift appears to be due in part to the obvious fact that where extensive artificial immunization has been carried out among children any increase in diphtheria will be more likely to affect adults.

Aside from the effect of the use of antitoxin and improved medical treatment

to prevention of deaths and of mass immunization programs in the prevention of clinical cases, the cause or causes of the natural decline in diphtheria is largely a matter of speculation. However, it seems apparent that one of the principal factors is a decrease in the pathogenicity of the prevailing strains of diphtheria bacilli. The disease in the North Temperate Zone has taken on more of the characteristics of tropical diphtheria with a high ratio of subclinical or immunizing infections to clinical cases.

**Control.** With the advance in knowledge of the frequency of inapparent infections, carriers and missed cases, and the failure of technical methods to reveal all such infections, it has become clear that to prevent the dissemination of diphtheria bacilli in a community is a formidable task. Nevertheless, it is equally apparent that the occurrence of a clinical case of diphtheria in a family provides a focus from which dissemination may take place. It has been shown that the risk of a clinical attack was far greater for intrafamilial contacts of a case than for the contacts of a casual carrier in the population. Some measure of restriction of the movements of members of the family group invaded by diphtheria is, therefore, justified.

All suspected cases of diphtheria should be isolated pending confirmation of the diagnosis. The patient should be kept at bed rest for a minimum period of two weeks. At the end of this time cultures should be taken from the nose and throat before release. Two consecutive negative cultures, taken 24 hours apart, should be obtained before discharge. If any of the cultures are positive at this time the laboratory should be requested to ascertain whether or not the organisms are toxigenic. If diagnostic laboratory facilities are not available, isolation may be terminated at the end of two weeks with a fair degree of safety.

All familial contacts should be placed under medical surveillance and examined daily for evidence of infection. Cultures should be taken from the nose and throat for diphtheria bacilli. Although the probabilities are that the older children and adults in the family are immune as a result of previous experience, either natural or artificial, this assumption should be safeguarded by keeping them under observation. The exposed younger children and infants, unless known to be immune, should receive an immediate injection of alum-precipitated toxoid. If the child has been previously immunized, this will act as a secondary stimulus or booster dose; if not, it will give the child the advantage of a primary stimulus before a potential infection has had time to materialize. On account of the danger of laryngeal diphtheria, infants that are not known to have been previously immunized should receive a prophylactic dose of antitoxin. This may be given at the same time as the injection of alum-precipitated toxoid, but in that event a second injection of toxoid should be made within three weeks.

Familial contacts found to have positive nose or throat cultures should be restricted until negative cultures have been obtained. Children with positive cultures should be restricted from play with susceptible children or attendance at school until two negative cultures have been obtained. Adult carriers whose occupations involve the handling of food or close association with children should be excluded from these occupations until shown by bacteriological examinations to be negative. The persistence of the carrier state in some individuals continues to be an annoying problem in public health administration. The local application of various antiseptics such as sodium ricin oleate, gentian violet, iodine, and mercurochrome has been

tried with discouraging results. Exposure to ultraviolet and deep x-ray treatments have been to no avail. Tonsillectomy and adenoidectomy are the most effective methods of clearing up carriers. Before the operation the patient's Schick test must be negative.

When a case of diphtheria has occurred in a school, institutional, military, or other group, daily medical examination of intimate contacts of the patient should be made for at least a week after last exposure. Search for carriers in large groups by culturing nose and throat is ordinarily not a profitable undertaking. Prevention of further cases depends upon the proper application of immunization procedures to exposed susceptibles, indicated by the history of previous immunization or by the Schick test.

Isolation and quarantine restrictions directed by the occurrence of cases in families, schools, institutions or military organizations will not materially affect the spread of diphtheria bacilli through the population of a community. It has been well established, however, that the occurrence of clinical cases of diphtheria can be reduced to the vanishing point by an effective long range program of active immunization. The program must provide for the follow-up of all births to insure the beginning of the immunization by giving two doses of toxoid, one month apart, between the second and sixth month, and the giving of a recall dose within 3 to 12 months. Children should be given a second immunization, or at least a recall dose, before entering school. It may also be advisable under some circumstances to give a booster injection of 0.1 to 0.5 ml. of alum-precipitated toxoid (preferably purified in preparation) to older children and adolescents living in communities in which diphtheria has not been recently prevalent (James and others, 1951).

With such a program, even in the absence of natural exposure to *C. diphtheriae*, there is a progressive decrease in the proportion of the population which is susceptible in the course of time. However, under conditions of practical public health administration, it is seldom possible to extend protection to every individual in a community. Not only are there some who escape immunization procedures for one reason or another, but there is also a not inconsiderable proportion of individuals who are poor reactors to the specific antigen. A small outbreak of diphtheria occurred in Baltimore in 1944 (Eller and Frobisher, 1945) at a time when it was estimated that upwards of 75 per cent of the children had been given toxoid at some time during their lives. Among the 123 cases which occurred, there was a record that 45 per cent had previously received toxoid; in an additional 18 per cent there was a questionable history of having previously received one or more injections of some form of diphtheria immunizing material. Similarly, Mattison (1944) investigated an outbreak in Kingston, New York, in which there were 28 cases. Eighteen were reported to have been previously immunized; 23 were among children of school age. It was estimated at the time that 75 per cent of the children of school age and 44 per cent of preschool children had received artificial immunization.

**Disinfection.** Disinfection has a place in controlling this infection in the home. The necessary measures to be taken during the course of the illness and at the termination of the isolation period should be carried out in accordance with instructions from a public health nurse.

A special cleansing with soap and water of floors, walls, door knobs, bed frames and other surfaces that have been contaminated will suffice.

**Prevention of Postdiphtheritic Paralysis.** It has been observed that postdiphtheritic paralysis is more frequent since the use of antitoxin than before the days of serum therapy. This is due to the fact that many cases now recover that would formerly have died. It is also due to the fact that diphtheria antitoxin is sometimes used too late. The prevention of postdiphtheritic paralysis, therefore, consists in giving *sufficient* amounts of antitoxin *early* in the disease. The antitoxin does not influence the paralysis after it has once appeared.

**Responsibility for Diphtheria Deaths.** People still die of diphtheria—usually because the diagnosis is not made early and because diphtheria antitoxin is not given in time.

Diphtheria antitoxin is a specific and sovereign remedy when given in sufficient amounts during the first 24 hours of the disease. Upon the first appearance of sore throat, fever, or other suggestive symptoms in persons who are exposed to diphtheria, and without waiting for bacteriological confirmation, a full dose of 3,000 to 10,000 units or more in proportion to weight should be administered without delay. It is absorbed more quickly when given *intramuscularly*. In very toxic cases, or for late use, it acts most quickly when given intravenously. In order to obtain the full lifesaving benefits of diphtheria antitoxin, it must be given early in the disease. Time is the most important factor (Stevens, 1931). When the damage to the cells has been done, it may be too late.

In a study of 1,000 deaths made by Carey (1919) of the Massachusetts State Department of Public Health, it is shown that the useful knowledge and facilities of dealing with diphtheria are utilized far too little. In 23.1 per cent of the cases, the patient was ill a week before the physician was called. In 4.2 per cent, the patients had been ill from one to two weeks before they received attention. In 7.6 per cent of the deaths, the disease was not recognized during life. In a number of fatal cases, the physician delayed antitoxin treatment by waiting for laboratory confirmation of the diagnosis. In not a single instance was the antitoxin given intravenously. A similar situation was found in New York City—"with a diagnostic laboratory service unsurpassed, with Schick test outfits, antitoxin serum, and active immunization outfits practically at their elbow, the physicians of New York were charged with insufficient or delayed utilization of these aids and with responsibility of continued prevalence of fatal cases of diphtheria." Every death from diphtheria should be

Table 1-7. Amount of antitoxin in the treatment of a case of diphtheria

	Mild Cases Units	Moderate and Early Severe Units *	Severe and Malignant Units *
Infants, 10 to 30 lbs. in weight under 2 years	3,000 to 5,000	5,000 to 10,000	7,500 to 10,000
Children, 30 to 90 lbs. in weight under 15 years	4,000 to 10,000	10,000 to 15,000	10,000 to 20,000
Adults, 90 lbs. and over in weight	5,000 to 10,000	10,000 to 20,000	20,000 to 50,000

\* When given intramuscularly use the larger amounts indicated.

investigated and the responsible party brought to task. The facts indicate the further need of education of both the profession and the public, in order to save lives from this and other preventable infections.

#### PREVENTION OF SERUM SICKNESS AND ANAPHYLACTIC SHOCK

Serum sickness is a syndrome which frequently follows the injection of horse serum into man. The symptoms usually come on about 8 or 10 days following the injection. The period of incubation is shorter if the person has had a previous injection of homologous serum. The syndrome consists of various skin eruptions, usually urticarial or erythematous in character; also fever, vomiting, edema, glandular and splenic enlargements, rheumatic-like pains in the joints and muscles and albuminuria. The eruptions may be either local or general, and sometimes resemble those of scarlet fever or measles. Serum sickness has nothing to do with the antitoxin, but is caused entirely by the foreign proteins contained in the horse serum. It may be produced with normal horse serum as well as with antitoxic horse serum, and is explained in terms of allergy. The occurrence and severity of the symptoms depend upon the amount of foreign protein injected and the sensitiveness of the individual. If concentrated antitoxic serum is used, the reactions are correspondingly lessened because smaller quantities of the foreign protein are injected, the albumins and certain other proteins having been eliminated by the partial purification. The concentrated antitoxin contains mainly serum-globulin.

Under certain circumstances, however, anaphylactic shock develops a few moments after the injection and may be fatal. H. F. Gillette collected 28 cases of collapse after serum injection, of which 15 died. Rosenau and Anderson brought together some 19 cases of sudden death following the injection of horse serum. This unusual and serious complication comes on within a few minutes of the injection, and is characterized by collapse, unconsciousness, cyanosis, labored respiration and edema. The heart continues to beat after respiration has ceased. The entire picture is an exact counterpart of the anaphylactic shock so readily produced by a second injection of horse serum in the sensitized guinea pig.

Contrary to the experimental work on serum anaphylaxis in the lower animals, the cases of sudden death in man usually follow the first injection of horse serum. Just how man becomes sensitized in these cases is not always clear. It may be by a previous injection of horse serum, or by eating horse meat, or by the introduction of small amounts of horse protein through wounds of the skin or through the respiratory tract; or hereditary transmission may account for the susceptibility.

Most cases of anaphylactic shock occur in healthy persons who give a history of asthma or discomfort when about horses. This is a practical and important point, and should be inquired into before horse serum of any kind is injected. Horse serum should not be injected into such individuals unless the indications are clear and then only with a statement as to the possible outcome. Desensitization may be tried or bovine serum substituted.

**Desensitization.** It is a question whether it is possible readily to desensitize man in a short time. In case hypersensitiveness is suspected, spaced injections of serum beginning with very small amounts subcutaneously may be tried. Hypersensitiveness may be inferred from an ocular or intradermal injection. There is, however, no

necessary correlation between local hypersensitiveness and general anaphylactic reactions.

Adrenalin is the best therapeutic agent to prevent and relieve serum allergy. Full therapeutic amounts should be used and this material in a syringe should be on hand ready for emergency use.

### VINCENT'S ANGINA (FUSOSPIROCHETAL DISEASE)

(*Fusospirochetalosis*, *Plaut-Vincent Angina*, *Ulceromembranous Angina*)

Vincent's angina is an infection associated with spirochetes and fusiform bacilli. It is characterized by inflammatory lesions of the mucous membrane, usually of the mouth. It remains on the surface, not affecting the membrane deeply. Its progress is slow and often chronic. Ulceration and pseudomembranous formation occur. If not the cause, it may be associated with the progress of pyorrhea alveolaris. The only local symptom may be pain and constitutional reaction may be absent. Sometimes there is moderate fever.

The name Plaut-Vincent disease is often given to this infection, after Plaut who described the organism in 1894 and Vincent in 1896. Leeuwenhoeck, the father of microscopy, doubtless saw the spiral micro-organisms with his crude lenses in 1683.

According to Smith (1932) the infection is caused by fusiform bacilli (*Borrelia buccale* and *Borrelia vincentii*) and spirochetes (*Treponema microdentium* and *Treponema mucosum*) acting in symbiosis with vibrios and cocci. The spirochetes and fusiform bacilli never appear alone in progressive lesions. They are normal inhabitants of the gums, but their numbers increase enormously when the local tissue resistance is reduced either by trauma or by deficiencies of certain vitamins, such as niacin and ascorbic acid.

The unsanitary conditions of military operations make fusospirochetal disease a war disease. It was prevalent during the American Civil War, the Franco-Prussian War, and the Spanish-American War. During World War I the disease prevailed in epidemic form and was called "trench mouth."

When the tonsils are involved because of the pseudomembrane, Vincent's angina is confused with diphtheria. The diagnosis is made by microscopic examination of stained smears. The yellowish gray membranous exudate is easily removed, leaving a raw bleeding surface. There may be a rapid ulceration of the tonsillar tissue resulting in a deep "punched out" ulcer which has sometimes been erroneously diagnosed as syphilitic.

Regions remote from the mouth and pharynx are often attacked. The more comprehensive term, fusospirochilosis, therefore is favored on account of the wide distribution of the lesions. There is a related group of infections characterized by necrosis and destruction of tissue, pseudomembranous formation in superficial lesions and a fetid odor, which occur not only in the tonsils, gums, cheeks, tongue, pharynx and larynx, but also in the eyes, ears, trachea, bronchi, lungs, esophagus, appendix, colon, and genitalia. Lesions even occur in the brain and other organs when the infection is carried internally as emboli in the blood stream. Members of this group of spiral organisms are responsible for such diseases as noma, the bronchial spirochetosis of Castellani, and fusopirochetal pulmonary gangrene and abscess (Smith, 1932), tropical ulcer, and pseudomembranous and phagedenic infections of the male and female genitalia.

**Prevention.** Vincent's angina is more often found in those who have unclean mouths, faulty fillings and other sources of irritation. Those who practice oral hygiene may also become infected. The infection is spread mainly directly, but occasionally indirectly. Eating utensils, towels, drinking cups, personal articles, and kissing are all operative. The infection is apt to spread among those who live, work and play together.

The first principle of prevention is to keep the mouth in a clean healthy condition. No decayed teeth or broken down roots should be allowed to remain. The mouth should be thoroughly cleansed by the use of a tooth brush and dental preparation (soap or salt water is more serviceable than many expensive dentifrices). Household remedies which are useful both in the prevention and treatment of Vincent's angina are hydrogen peroxide (equal parts), potassium permanganate (1:5,000), and one of the pleasant sodium perborate preparations. All these when freshly prepared liberate oxygen and theoretically are best for this anaerobic infection. The gums should be properly massaged with a tooth brush or the finger. It is possible for a clean mouth to become infected, but healthy vigorous gums and mucous membrane are resistant.

### WHOOPING COUGH

(*Pertussis*)

JOSEPH A. BELL, M.D., DR.P.H.

Whooping cough is a communicable disease caused by infection with *Hemophilus pertussis* (Bordet-Gengou bacillus) and characterized by catarrh of the respiratory tract with paroxysmal cough frequently ending in whooping and vomiting. The long drawn-out course of the disease is distressing and interferes with nutrition and rest. A fatal bronchopneumonia is not uncommon, especially in infants. The infant mortality rates reported for whooping cough have generally exceeded those of other common communicable diseases but have dropped precipitously during the past few years.

Epidemic whooping cough was first described by Baillou of Paris in 1578. In 1906 Bordet and Gengou isolated and described the causative agent of the disease.

Even then interest in the disease was thin. The vigorous attack which served to solve so many other problems in preventive medicine was lacking for a long time.

Willis, in 1674, said, "Whooping cough is left to the management of old women and empirics" and such is still largely the case. The attitude of indifference with which the general public regards whooping cough contrasts strangely with the fact that it is one of the most distressing and fatal of the acute infections of childhood. Up to recent years the lack of specific prophylactic and therapeutic agents contributed to this attitude of indifference.

**The Disease.** The incubation period of whooping cough is usually 7 to 10 days, but it may possibly range from 4 to 16 days.

The onset is insidious and in many instances the patient appears to develop a cold. The typical clinical course may be described in three stages: (1) catarrhal, (2) paroxysmal, and (3) decline. The catarrhal stage lasts about 10 days. During this time if there is cough without other physical signs, and leukocytosis with a relative lymphocytosis, whooping cough may be suspected and the diagnosis confirmed bacteriologically. Not until the paroxysmal stage, which usually comes on two to four weeks after exposure, can the disease be recognized clinically with any certainty. The paroxysm consists of a repeated series of explosive coughs in rapid succession without opportunity for inspiration, ending with a long inspiratory whoop. The violence of the coughing spasm may be necessary to raise typical, very tenacious mucus. The stress causes cyanosis, the face is livid, and the strain often ends with vomiting and occasionally nosebleed. The paroxysm is distressing and leaves the child exhausted. Nutrition suffers and complications are invited. The number and severity of paroxysms vary greatly. Whoop may be absent in mild cases and especially in adults and infants. The second stage lasts four to six weeks, passing gradually into the stage of decline, when attacks become less frequent and finally disappear. Paroxysms sometimes recur six months or more after recovery, in the event of a respiratory infection.

**Occurrence.** Pertussis is a common disease of childhood; it occurs throughout the world and at any season of the year. Susceptible children are constantly being born into the population, and in areas where such susceptibles have sufficient contact to permit a continuous chain of new infections, the disease remains endemic. In smaller, more isolated areas where a continuous chain of susceptibles is not available, the disease cannot maintain itself and it disappears, sometimes for a period of years; later, when it is reintroduced to the area, a large number of susceptibles has accumulated and an epidemic often results. In the relatively isolated Faroe Islands, Madsen reported a large epidemic about every seven years. In general, however, aside from a slight but definite seasonal variation, regular recurrences of pertussis are hardly discernible. The seasonal variation of pertussis is strikingly small. The ratio of the number of cases at the peak and trough is 2:1 to 3:1, whereas for measles and other common communicable diseases the ratio may be 50 or more to 1. In the United States, the seasonal peak is in late March or early April, with the trough in October. In general, the reporting of cases of pertussis is very poor, and this is also true in the United States. The disease is definitely one of childhood with comparatively few cases occurring after the age of 12. Most cases occur in the age group 1 to 8 years, and in this age group the young cases are frequently the result of secondary contact in the family household.

Although the occurrence of cases by sex is almost equal, the sex distribution of pertussis mortality is unique among the infectious diseases. Females more often die from pertussis than males. This peculiar sex difference appears to be true for all ages, races and climates, and has existed for many years.

Mortality in pertussis is more completely reported than morbidity. The accuracy with which the actual cause of death is reflected by mortality reports needs a little elaboration. For example, in 1940 the U. S. Mortality Reports show 2,926 deaths from pertussis, and in 77 per cent of these influenza or pneumonia was listed as the secondary cause of death. In addition, there were 115 reported deaths from other causes where pertussis was listed as the secondary cause. There is a divergence of opinion as to whether pertussis mortality is under or over reported but in either event the proportionate error is probably small.

The age distribution of deaths is striking when contrasted with the age distribution of cases. The over-all case fatality at all ages is less than 1.0 per cent, and the case fatality is even lower in late childhood but high in infancy. Ninety per cent of the deaths occur before the third birthday and more than 70 per cent before the first. Actually, more deaths are reported due to pertussis during the second month of life than during any other month. The infant deaths from pertussis are generally higher than those from measles, diphtheria, scarlet fever, poliomyelitis or tuberculosis. The public health hazards of the disease are not to be measured exclusively by the number of deaths. The age of death is extremely important. When deaths in children are prevented with no resultant disability many person-years of productive life are gained, but when deaths at middle age are prevented only a few person-years of productive life are gained. In addition to the hazard from death the long, drawn-out, and distressing course of the disease causes considerable anxiety, suffering, inconvenience, and disability.

The death rate from whooping cough is much higher in Latin America than in the United States. Within this country during the years 1941 to 1945 the highest death rates were reported in the East South Central States (Kentucky, Tennessee, Alabama and Mississippi), and the lowest rates in the Pacific and New England States. In the Northern and Central States the peak of whooping cough mortality is in March and April, with a tendency to a slight rise again in July and August. In the Southern States the peak of mortality is in June and July.

The race distribution of deaths is interesting. The reported Negro death rates are two to three times the rates for whites and the Indian rates are eight times as high. The population base for the latter is known to be inaccurate. The higher Negro death rates may possibly be due to the urban-rural and age distribution of cases and possibly to inadequate medical care. The rural death rates from pertussis are generally higher than the urban rates. Luttinger (1917) found that 160 out of 162 consecutively reported deaths from pertussis had occurred in children living in tenements of New York City, and in over one half of the cases the mother worked away from home every day, and the average number of rooms occupied by the family of five or over was less than two and one-fourth. In addition, he found a death rate of 4.3 per cent in 161 cases investigated from tenements as compared with no deaths among 182 cases in private practice, including cases with illness and complicating bronchopneumonia.

There has been a downward trend in the rates for pertussis mortality in the

United States for many years. For example, the median crude rates per 100,000 population for each 5-year period from 1916 to 1950 were: 10.5, 8.1, 6.2, 3.9, 2.3, 1.9 and 0.4. The infant mortality rates per 1,000 live births follow a similar trend: 2.4, 2.1, 1.9, 1.4, 0.9, 0.6 and 0.2. Proportionately the decline has been dramatic in recent years. Much of this can be attributed to vaccines and specific therapy for complications, and further declines are anticipated as more effective vaccines and specific therapy, both for complications and for the disease itself, are more widely used.

**Etiology.** The Bordet-Gengou bacillus (*Hemophilus pertussis*) was isolated and described in 1906. The experiments of Rich and others (1932) on chimpanzees offer evidence of the specific role of the Bordet-Gengou bacillus in the etiology of pertussis. Three animals which received filtrate of sputum from pertussis patients developed only typical colds in five to seven days. Animals receiving unfiltered sputum also developed a cold, after recovery from which catarrhal symptoms appeared, and these in turn were followed by spasmodic cough accompanied by leukocytosis and relative lymphocytosis. Cough plates were all positive for *H. pertussis*, and pure cultures caused catarrhal symptoms followed by cough when introduced into normal chimpanzees. In addition, the blood of animals developing symptoms from unfiltered sputum or cultures showed complement-fixing antibodies for the Bordet-Gengou bacillus (MacDonald and MacDonald, 1933).

The present belief that the Bordet-Gengou bacillus is the cause of pertussis is based on: (1) the occurrence of the specific complement-fixing antibodies described by the original workers and since repeatedly confirmed, (2) the demonstration of the bacilli by cough plate or nasopharyngeal culture in 75 to 95 per cent of cases early in the disease, (3) uniform failure to find the organism apart from the clinical disease and those intimately exposed, (4) results of experiments on monkeys, (5) the experimental human transmission of the disease, and (6) the selective prevention and amelioration of symptoms through specific vaccine prophylaxis.

**Bacteriological Diagnosis.** The cough plate method was suggested by Mauritzen and was first used extensively by the Danish Serum Institute. The nasopharyngeal swab method is more practical and thus more efficient for bacteriological diagnosis. It consists of swabbing the nasopharynx by passing a fine copper wire, tipped with a small amount of cotton, through the nose. The culture medium is essentially that described by Bordet-Gengou and consists of ground potato with glycerin, agar, and 20 to 30 per cent blood. Selective bacteriostatics such as penicillin 0.2-0.3 unit per ml. assist in preventing overgrowth by other organisms. The plates should be freshly made and preferably not over one week old. The plates must be incubated for at least three to four days because the colonies develop slowly. They are hemolytic and small, smooth and raised, and resemble a particle of quicksilver. The organisms are identified as very short Gram-negative rods which agglutinate with the specific antiserum. Care must be taken to distinguish them from *H. influenzae* and parapertussis. The latter was described by Kendrick as an antigenically different organism causing symptoms similar to pertussis.

**Transmission.** Whooping cough is one of the more readily communicable of the group of respiratory diseases. The infective agent is carried in the secretions of the upper respiratory tract. It is spread by human contact including droplet infection and contaminated fomites.

Whooping cough is most communicable during the catarrhal and early paroxysmal stage. The disease may be transmitted during the latter part of the period of incubation, for the Bordet-Gengou bacillus has been found a few days before the start of the catarrhal stage. Infectivity wanes as the paroxysmal stage wears on. Using the now obsolete cough plate method for bacteriological diagnosis, the percentages of *H. pertussis* isolations at various stages of the disease are shown in Table 1-8. These figures were reported by Kristensen (1933) from the Danish Serum Institute, Copenhagen, which include Madsen's figures (1925). Using the newer nasopharyngeal swab technic the percentages of *H. pertussis* isolation at various stages of disease have the same general trend but are much higher and approximate 90 per cent.

These facts have been confirmed by many, although the actual percentage of positives found at the various stages varies. All observers note a sudden drop of organisms between the fourth and fifth weeks of the paroxysmal stage, and then a rapid disappearance. Madsen states that in Denmark children with negative cough plates are returned to school after the fourth week, though still whooping. The period of greatest communicability corresponds to the period when large numbers of pertussis colonies are recoverable by culture.

Healthy *carriers*, in the exact sense of the word, are unknown in spite of many attempts to demonstrate them bacteriologically. On the other hand, adults who have previously had the disease are apt, when exposed to pertussis, to contract a cold with cough lasting a few weeks. This is really a mild second attack of whooping cough, for the specific micro-organisms have been demonstrated repeatedly. Furthermore, epidemiologic investigators have traced infections in children to just such mild and missed cases in adults. These missed cases constitute a very small proportion of the total cases of whooping cough.

Table 1-8. Results from examination of 2,144 pertussis patients at the Danish Serum Institute

	Number of Pertussis Patients	Number of Patients with Bordet-Gengou Bacillus	Per Cent of Positive Bacillary Results
Catarrhal stage	378	247	65.3
Convulsive stage, 1st week	837	486	58.1
Convulsive stage, 2nd week	441	231	52.4
Convulsive stage, 3rd week	210	84	40.0
Convulsive stage, 4th week	104	35	33.7
Convulsive stage after 4th week	174	13	7.5

**Immunity.** Whooping cough at one time or another affects almost every member of a community; by the time adult age is reached, about 78 per cent have had a recognized attack. This percentage is being rapidly reduced due to a more extensive use of effective vaccines. The greatest incidence apparently is between six months and five years of age. Very few cases occur during the first few months of life, but the largest number of deaths occur at this young age. After five years the severity decreases with age. One attack confers a definite, prolonged, but not always complete immunity.

*Second attacks* take the mild form mentioned above and are of little significance to the individual. They are, on the other hand, of considerable epidemiological

interest, for bacteriological studies have shown them to be more common than formerly supposed.

**Specific Prophylactic Immunization.** During the past 40 years many attempts have been made to prepare and demonstrate the efficacy of prophylactic pertussis vaccines. The results of early studies were unconvincing mainly on account of inadequate epidemiologic controls. In addition, some of the vaccines have been nonantigenic. In 1931, Leslie and Gardner classified cultures into four antigenic types. Old cultures fell into types III and IV and were rough, avirulent, and antigenically ineffective. Thus, an experimental basis was established for the empirically known fact that only fresh preparations of recently isolated, "smooth" strains should be used for bacterial vaccines. Using fresh isolated cultures, the vaccine reports of Madsen in Denmark and Sauer in the United States and others were encouraging. The controlled studies of Kendrick and others indicated that the vaccine they used gave definite protection, but the carefully controlled studies of Doull and others showed no prophylactic value to the vaccine they used. Since 1938, many studies in the United States have adequately demonstrated that various vaccines have definite prophylactic value. The studies in England, however, showed that their vaccines had no value until the 1951 report of an excellent and extensive study using various vaccine products. All vaccines used gave substantial protection but one was much better than the others. The best vaccine gave very good animal protection. In 1947, Kendrick described a mouse protection test which has been developed to permit comparison of the mouse protective potency of various pertussis vaccines in a standardized manner. Vaccine products sold under license of the U. S. Public Health Service are now standardized in mouse protective units not significantly different from a reference standard. The hope is entertained that this will eliminate many of the possibly ineffective vaccines in the United States. It is generally thought that the mouse protection test when properly carried out under standardized conditions is a good index of vaccine antigenicity for humans.

In 1938 Harrison and others introduced alum-precipitated pertussis vaccine with the hope that two doses would give substantial protection and be practical for general public health use. In 1941, Bell showed that two small doses, a total of only 20 thousand million organisms, of an alum-precipitated product gave substantial protection against clinical attacks of pertussis even when given to children as young as two months of age. This opened the door for the general use of pertussis vaccine mixed with alum-precipitated diphtheria toxoid. Many reports confirm the value of such a mixture. In one intensive study, two small doses of the mixed product given with a month's interval between doses not only gave substantial protection against clinical pertussis, even when given at two months of age, but also gave better protection against diphtheria, as measured by Schick tests performed one year after immunization, than the same quantity of alum-precipitated diphtheria toxoid alone. Actually, the protection against diphtheria was as good when the mixed product was used at two months of age as when the unmixed product was used at six months of age. Most investigators of clinical protection, when using the fluid product, have used a total of 70 to 120 thousand million organisms in three to five doses at intervals of two weeks. With the alum-precipitated product, a total of 20 to 45 thousand million organisms have been used effectively in two or three doses with a month's interval between doses. In the United States the vaccine is now standardized to contain 12 mouse protective units per immunizing dose.

There are so many possible variables in the occurrence and recognition of clinical pertussis, and in various vaccine products and their method of use that it is difficult to assess accurately and quantitatively the prophylactic value of pertussis vaccines. In general, 80 per cent of young susceptible children develop a clinical attack following family household exposure to the disease, whereas only 10 to 30 per cent of vaccinated but otherwise similar children, develop a clinical attack following such exposure. It is likely that still greater prevention results in less intense and less prolonged exposure. All in all, in such a prevalent disease, cases are not uncommon in vaccinated children. Nearly all investigators agree that the vast majority of such cases are extremely mild. This clinical impression has been substantiated by careful and direct epidemiologic study. In the United States, the average annual urban attack rate of pertussis in young susceptible preschool children kept under surveillance for the occurrence of the disease generally ranges from 8 to 12 per cent. The attack rate in similar, but vaccinated children, depends upon many variables and is generally reported to range from less than 1 to 3 or 4 per cent. The usual incidence of cases reported to health departments is much lower on account of incomplete reporting. In 1945, Garvin reported that beginning in 1936 approximately 75 per cent of preschool children in Shaker Heights, a community of 25,000 people, had been given pertussis vaccine, whereas only a small per cent of such children in the nearby large city of Cleveland, Ohio, had been immunized. For the seven years prior and since 1936, respectively, the reported average annual incidence of pertussis in children under five years of age per 100,000 population was 290 and 35 for Shaker Heights, and 187 and 160 for Cleveland. In addition, as stated above, there appears to be a more precipitous drop in pertussis mortality rates in the United States during the past several years when vaccines and better methods of treatment of complications have been more extensively used. During a period when the annual number of births has increased from two million to four million in the United States, the annual number of deaths from pertussis has decreased from around 10,000 to less than 500. All in all, pertussis vaccines are generally accepted for public health use in the United States, since they can be mixed with alum-precipitated diphtheria toxoid and given with little added inconvenience, and they result in substantial protection known to last for several years in a large proportion of children, with amelioration of the distressing clinical symptoms in most of those not completely protected. For many years the American Public Health Association has recommended that all children be immunized against smallpox and diphtheria and now the recommendations include pertussis vaccine.

Vaccines have been used for the treatment of children exposed to pertussis and the results have not been convincing, particularly because of the lack of acceptable epidemiologic controls. In general, the reported successes have largely been following the use of vaccine in children's institutions where one or more cases have been introduced. In such experiences the difficulty of obtaining adequate controls is obvious. Even if a good vaccine had no value when given after exposure, it might still be beneficial in such circumstances because many children would receive it prior to effective exposure; it would be very difficult for one or two cases to expose effectively all other children simultaneously in a sizable institution. How many days it takes for protective immunity to be established following vaccination is unknown; certainly it is established within a few months and perhaps less than one month.

**Specific Treatment.** A brief passive immunity may be conveyed to young chil-

dren by the administration of appropriate amounts of convalescent serum or similar agents. The risk of homologous serum jaundice from the use of human serum must be kept in mind. Immune serum may be used for treatment of severe cases or for prevention in young infants after exposure. Reports indicate that they are efficacious, but convincing proof for their widespread general use is not at hand.

Complications following secondary infection with pathogens should be treated with the sulfa drugs or antibiotics specific for such infection.

In animal experiments, streptomycin appears to have little specific effect on *H. pertussis* infection. As with serum, the clinical value is encouraging but not thoroughly convincing. Aureomycin is dramatically specific in curing mice infected with *H. pertussis*. Chloramphenicol and terramycin appear to have a similar action. Early reports on their clinical use are extremely encouraging. An unpublished report of Bell shows that after three or four days of aureomycin treatment in 100 cases the positive nasopharyngeal cultures were reduced from 80 to 20 per cent. When given early in the course of the disease, aureomycin, terramycin, and chloramphenicol appear to modify the severity and shorten the duration of illness. If this reflects a substantial reduction in the period of infectivity, the prompt recognition and treatment of cases, it will do much to ameliorate the hazards of pertussis.

**Prevention.** With our present knowledge, there is good opportunity to do much in the amelioration of the health hazards of pertussis. The practical difficulties of controlling the spread of infection are evident. During the long catarrhal stage of whooping cough, communicability is high, and diagnosis difficult. Many lives may be saved by simply delaying the age incidence. Infants can and should be protected. Education of the public to realization of the seriousness of the disease is necessary for success.

All susceptible children of preschool age, i.e., under five years, should be vaccinated against pertussis. Young infants living under conditions where the risk of exposure is great, those living in institutions and in households with older susceptible children should have active immunization started by the time they are two months of age, particularly if pertussis is then prevalent in the community. Other children should have immunization started by the time they are six months of age. An alum-precipitated mixture of pertussis vaccine and diphtheria toxoid can be used effectively for simultaneous immunization against both diseases. Tetanus toxoid may also be included. Reinforcing (booster) doses of pertussis vaccine may be advisable within a year and at two or three years of age.

*Early diagnosis and prompt reporting are essential.* When a case is reported it should be isolated. This, however, presents practical difficulties. It is not good for a child with whooping cough to remain confined for weeks; it is a handicap to deprive him of the benefits of sunshine, fresh air, and play. When the patient is permitted to be out-of-doors he must avoid contact with susceptible persons and not go to school, theater, church or public assembly, or ride in street cars or public vehicles. Children should go out only when accompanied by an intelligent caretaker as a protection to others.

Immediate investigation of contacts should be carried out, with especial attention to those under two years of age. Susceptibles should be placed under observation and a bacteriological diagnosis sought when early symptoms develop.

In whooping cough, even more than in most other acute infectious diseases, good

nursing and medical care are important, particularly for children under two years of age. Each community should provide adequate medical care for young children with pertussis, whose guardians cannot provide such care.

Laboratory facilities for bacteriological diagnosis should be provided.

After the paroxysms are established, communicability gradually decreases and becomes negligible for ordinary nonfamilial contacts in about three weeks, even though the sporadic cough with whoops may persist. The shortening of the quarantine period will promote cooperation of both laity and physicians by decreasing the hardship of isolation.

Schools need not be closed on account of whooping cough. Daily inspection of pupils when pertussis is prevalent may achieve better results. The patient should be separated from susceptible children and excluded from school and public places during the most communicable period of the disease, i.e., for 7 days after exposure to 21 days after onset of typical paroxysm. Susceptible children who are household contacts of a case should be similarly separated for two weeks after last contact but may be permitted to attend school if daily examination by a physician or a nurse finds them free from cough and catarrh. Other members of the household may be allowed to follow their usual occupations.

The chief measures for control of pertussis are prophylactic vaccination of all infants, protection of young children from exposure, and adequate medical care of cases.

### MENINGOCOCCIC MENINGITIS

(*Epidemic Cerebrospinal Meningitis, Cerebrospinal Fever*)

Acute purulent cerebrospinal meningitis may be caused by any one of a number of pathogenic bacteria by extension of an infectious process, either directly or through the blood stream to the meninges. Epidemic cerebrospinal meningitis, or cerebrospinal fever, is caused by the meningococcus. The clinical characteristics of the disease were first described by Vieusseux in connection with an outbreak which occurred in Geneva, Switzerland, in 1805. It was not until 1887 that Weichselbaum established the relationship of the meningococcus (*Neisseria meningitidis*) to this disease. This led to more exact diagnosis and an understanding of its pathogenesis.

**The Disease.** There are three stages in the development of meningococcus infection: (a) localization in the nasopharynx, (b) invasion of the blood stream, (c) involvement of the meninges. The variation in the clinical pattern depends upon the rapidity of progression through these three phases and their duration. On the one hand are the cases in which the clinical picture is that of a sepsis with little or no

involvement of the meninges. The meningococcemia may be transient and recovery follow after a brief illness of protean character, or it may be persistent, lasting over several days or weeks. At the other extreme are the cases which pursue a fulminating course, the patient becoming stuporous, passing into coma and dying within four to eight hours. Of 216 cases reported during an epidemic in Memphis, Tennessee, in 1929, 37 died within 24 hours and 8 more within 48 hours. If the blood stream invasion is a marked feature, it is manifested by an irregularly distributed petechial, purpuric or maculopapular skin eruption. These vascular lesions are due to thrombo-embolic involvement of the capillaries. They occur in from 10 to 70 per cent of patients, the frequency varying somewhat with different epidemics. Because of this characteristic, such designations as "sinking typhus," "cerebral typhus," and "spotted fever" appeared in the early writings indicating confusion with typhus fever.

In the cases commonly seen both in epidemics and occurring sporadically, the blood stream phase is transient and succeeded rapidly by symptoms indicating involvement of the meninges. The incubation period is 2 to 10 days. There is a sudden onset with malaise, followed rapidly by stiff neck, nausea and vomiting. The temperature is irregularly elevated. The patient suffers from severe headaches and muscle pains and is usually delirious or stuporous, sometimes comatose. The musculature becomes rigid with contracture of the hamstring muscles (Kernig sign).

The course of the disease has been radically changed by the use of chemotherapeutic agents. Before the era of sulfa drugs, complications were frequent, many cases had a protracted course and were left with distressing sequelae. The case fatality rate ranged from 50 to 70 per cent in some outbreaks. Under modern conditions of treatment (Dingle and Finland, 1942) there has been a dramatic change. The case fatality rate has been reduced to less than 5 per cent. The deaths which occur are in those in whom the disease pursues a fulminating course; there is a fatal issue before effective therapy can be instituted. When conditions permit early institution of treatment with sulfonamide drugs, there is improvement in general condition and the temperature shows rapid return to normal, usually within 36 hours. The sensorium is usually clear within 48 hours, but headache and nuchal rigidity may persist for as long as a week.

**Bacteriologic Diagnosis.** Meningococci can be demonstrated in almost every case of cerebrospinal fever from one or more of three sources, namely, the nasopharynx, the blood, the cerebrospinal fluid. In fulminating cases, the Gram-negative intracellular or extracellular, biscuit-shaped diplococci may be seen directly in stained smears of capillary blood or of blood from a particular purpuric lesion. When meningeal symptoms are present a lumbar puncture is done and typical organisms may be demonstrated from direct smears made from the spinal fluid and stained with Gram. As the meningococcus is a very fastidious organism in its growth requirements, and extremely sensitive to cold and drying, recovery of these organisms by culture from the nasopharynx, the blood or the spinal fluid, requires specialized technics with appropriate media. For final identification, pure culture study and serological typing is necessary. According to Branham (1950) the following characteristics distinguish the meningococcus from other closely related *Neisseria*: "A Gram-negative coccus, usually occurs in pairs with flattened adjacent sides, which ferments dextrose, and maltose with the production of acid, forms characteristic colonies, does not produce pigment, usually grows only at body temperature.

and is as a rule at some time agglutinable by polyvalent antimeningococcus serum."

The meningococcus is a strict aerobe. Growth, especially from small inocula, however, is markedly enhanced by the addition of 5 to 10 per cent carbon dioxide to the atmosphere—a fact of importance in diagnosis and planning of studies. It is unusual to obtain proliferation at temperatures below 30° C or over 40° C, and the optimum is between 35° and 37° C.

These organisms are very susceptible to bactericidal agents. Drying, cold and the common germicides readily kill them even in low dilution. Over 98 per cent of case strains are inhibited in vitro by 0.5 mg. per cent or less of sulfadiazine. Penicillin is inhibitory in a concentration of from 0.1 to 0.5 units per ml. Tolerance, however, is rapidly developed in vitro to these therapeutic agents.

**Types of Meningococci.** When the meningococcus was identified by Weichselbaum in 1887, it was thought to be a homogeneous species. In 1909, however, Dopter isolated a strain which differed serologically from the original and called it parameningococcus. During World War I, this led the French investigators to classify meningococci into two main groups, Group A and Group B, recognized by British investigators as Group I and Group II. By the more refined technic of agglutinin absorption, Gordon and Murray recognized four types. Other investigators recognized the validity of this subclassification but there was some disagreement upon terminology and the antigenic range to be included in a single type. In the United States, it is believed to be impractical to distinguish between Type I and Type III which are classified jointly as Group I. Type II strains are not homogeneous serologically and are, therefore, more appropriately designated as Group II. A number of strains formerly classified as Type II, or Group II, have recently been separately designated and are now referred to as Group IIa. Type IV has not been isolated in the United States from cases and is so uncommon that its classification seems unwarranted at the present time. Some strains of meningococci isolated from the nasopharynx do not seem to fall into any of the known groups. They can be agglutinated by polyvalent horse sera but not by the specific rabbit or chicken sera employed in type indentifications. However, they are unimportant in the causation of the disease.

**Carriers.** In 1901, von Albrecht and Ghon called attention to the fact that not only patients but many apparently normal individuals, who, in so far as was known, had not had any contact with cases of meningitis, harbored meningococci in their nasopharynx. The existence of "carriers" afforded an explanation for much that had been obscure as to the spread of this disease. This observation was confirmed and many studies were conducted to determine the frequency and importance of these "carrier" infections during the epidemic and interepidemic periods. Since World War I, of 1914-1918, it has been realized to an increasing degree that cerebro-meningitis is in a sense a complication occurring occasionally among those who harbor the meningococcus in their nasopharynx. An excellent summary of the early studies is contained in the chapter on the "nasopharynx as the Habitat of the Meningococcus" in the monograph by Netter and Debré (1911). The isolation and identification of the meningococcus from the nasopharyngeal secretions is subject to many sources of technical error; but when these are minimized this micro-organism is constantly found in the nasopharyngeal secretions of the patient during the first

days of the malady. The carrier rate among those in the vicinity of patients has been found to vary; some observers reporting 5 per cent of carriers among the contacts, others as many as 50 or 60 per cent. The differences were thought to be due to the technical methods, the stage of the outbreak when the contacts were examined, and to environmental conditions. From information then available, Netter and Debré concluded that the intensity of the outbreak and the carrier rate corresponded. This point of view was confirmed by the studies of Glover (1920) on the control of cerebrospinal fever among troops in training in England in the course of World War I. Glover suggested that a "non-contact carrier rate" of 20 per cent or more was a danger signal and preceded the occurrence of cases of cerebrospinal fever in a military organization. However, Dudley and Brennan (1934), Rake (1934) and others, have found high carrier rates in populations where cases of meningitis were not occurring. Reviews by Maxcy (1937), Dingle and Finland (1942), and Aycock and Mueller (1950) questioned a fixed quantitative relationship between a crude carrier rate and a case rate. Apparently the ratio of nasopharyngeal infections to the occurrence of cases varies with many factors and conditions and is determined in part at least by the potential pathogenicity of the prevailing strains of meningococci.

According to Branham and Carlin (1942) more than 90 per cent of the cases of meningococcic meningitis during epidemics are due to Group I, whereas Group II is more often responsible for sporadic cases. By far the greater number of carrier strains recovered during nonepidemic times are Group II. Chronic carriers are especially apt to harbor Group II. During World War II, typing of strains isolated from cases throughout the Army indicated that 91.6 per cent were Group I. In an intensive study made at one Army camp, Phair and Schoenbach (1944) found that all of the cases of meningitis were associated with Group I meningococci, but in a group of 99 normal men, 53.5 per cent harbored meningococci Group I in their nasopharynx, 38.4 Type IIa and 50.4 Group II. This same group was kept under observation for 10 weeks and during this time were cultured three times weekly. The average composite prevalence rate was 40 per cent but 92.9 per cent were infected some time during the study period. Of the 92 men with positive cultures, 44 had infections classified as persistent under reasonable definition, and an approximately equal number had only transient infections. Cultures from some men were negative throughout the study period; spontaneous recovery from infection occurred in many; in others, infections of one type were followed, interrupted or accompanied by infection with another type. The extensive observations upon military personnel by Aycock and Mueller (1950) at Fort Devens and Camp Edwards, Massachusetts, led to the conclusion that the base upon which meningitis was occurring was the Type I meningococcus carrier rate. These studies confirmed the concept that the spread of meningococci is primarily at the subclinical level and that there is a carrier epidemic for the most part devoid of characteristic clinical manifestations preceding and accompanying the much smaller case epidemic. Moreover, it has been pointed out by Phair and Schoenbach (1944) that the frequency of cases occurring in successive time periods is related to the incidence of new nasopharyngeal infections with the prevailing pathogenic type of meningococci rather than the crude carrier prevalence rate at any given time.

Immunity. Distinction should be made between immunity to clinical attack, i.e., to invasion of the blood stream and or localization in the meninges, and

immunity to infection, i.e., to the growth of the organism in the nasopharynx. Evidently there is a high degree of natural immunity to clinical attack since only a small proportion, perhaps one in 1,000, of those who harbor the organism in the nasopharynx develop meningococcemia or meningitis. The degree of acquired immunity resulting from clinical attack is unknown but presumably durable. Second attacks are extremely rare. Since the morbidity rate, even during an epidemic, is so low (the annual rate rarely exceeds four per 1,000 individuals) the probability of observing a second attack in the same individual is extremely small. The problem is further complicated by the existence of immunologically variable meningococcic types. The formation of antibodies as a result of disease can be demonstrated by agglutination, mouse protection, quantitative precipitin reaction, complement fixation and bactericidal technics.

That some immunity is acquired is suggested by (a) the decrease in the attack rate with advancing age in civil populations, and (b) the greater susceptibility of recruits in military populations. With regard to civil populations, it has long been known that the attack rates from this disease were highest in infants and young children. Table 1-9 illustrates a typical civilian epidemic experience. The attack

Table 1-9. Age distribution meningococcic meningitis, Santiago, Chile, 1942

Age	Population	Cases		Deaths	
		Number	Attack Rate Per 100,000 Population	Number	Case Fatality (Per Cent)
Under 1 year	38,060	309	812	102	33.0
1-4	127,486	770	604	190	24.7
5-9	122,814	612	498	77	12.6
10-14	112,902	541	479	31	5.7
15-19	146,019	384	263	32	8.3
20-24	147,671	245	166	17	6.9
25-34	234,581	355	151	36	10.1
35-44	159,635	215	135	32	14.9
45-54	106,333	93	87	14	15.1
55-64	56,800	34	60	10	29.4
65 +	38,306	22	57	12	54.5
Unknown		6			

Adapted from Horowitz and Perroni, Arch. Int. Med., 74:365, Table 2, 1944.

rate was six to eight times as high among infants as it was among old people. On the assumption that all ages are equally exposed in the family, this age distribution is interpreted as indicating a gradual acquisition of immunity with advancing age. With regard to military populations, it has long been known that the attack rate among recruits was much higher than that among seasoned men. For example, Cook (1936) found that the attack rate in men with less than three months service was 10 to 46 times as great as that of men with more than one year of service. During 1942 and 1943 in the U. S. Army, Sartwell and Smith (1944) observed that of a total of 1,337 cases, 57 per cent occurred within three months after induction. Only rarely did men who had been in the Army more than a year develop meningitis.

Among military personnel, therefore, environmental age appears to be analogous with chronological age in civil populations with respect to the incidence of cerebrospinal fever. Since the clinical attack rate is too low to account for this acquired immunity, it appears probable that it is the result of experience with the meningococcus as a subclinical infection of the nasopharynx. It should be noted that an individual can harbor a specific antigenic strain of meningococcus in the nasopharynx for a period of time, then become negative on culture, and later harbor again either the same or a different antigenic strain (Phair and Schoenbach, 1944). Rake (1934) making repeated examinations on individuals working on one floor of a unit building of Rockefeller Institute in New York City, found four chronic carriers who harbored the organism from 21 to 26 months and were still positive when last observed. Evidently the resistance acquired to growth of the organism on the mucous membrane of the nasopharynx is of low order. Such experiences are, however, apparently sufficient in some individuals to confer immunity against clinical attack.

**Mode of Transmission.** The mode of transmission is essentially that described for other infections of the respiratory tract. It is to be noted, however, that the meningococcus dies very quickly outside the body when exposed to sunlight or drying. There are no extrahuman reservoirs of the disease. Propagation is maintained by person-to-person transfer. The contact must be of an intimate sort which permits nasopharyngeal secretions of one individual to reach the nasopharynx of another rather directly. This explains the association of the disease with crowded living conditions.

**Occurrence.** For the most part the disease has an endemic prevalence. Rarely is there more than one case in each household that is invaded. It is never long absent from any large population group. Sporadic cases occur throughout the year, the disease being most prevalent during the winter and spring months. Small outbreaks occur from time to time among troops in military installations, among inmates of refugee camps, prisons, orphanages and other institutions.

There are periods during which the disease is widely prevalent over large geographic areas. In these major epidemics, the spread may involve a single country or several adjacent countries, progressing gradually from one area to another, over a period of years. From a study of medical literature, Hirsh traced the occurrence of epidemic meningitis from about 1805 to 1886. He recognized four periods of unusual world prevalence. The movements of epidemics have been reviewed by Low (1916), Hedrich (1931), and Gover and Jackson (1946) from analyses of statistical reports of cases and deaths. Since 1916, there have been four distinct epidemic waves in the United States. The first began during World War I, reaching its maximum in 1917, and subsided slowly through 1924. The second period was of 10 years duration, from 1925 to 1934, with its peak in 1929. The third cycle extended from 1935 to 1940, with 1936 as the peak. In the last epidemic, cerebrospinal meningitis became increasingly prevalent in the United States just after the beginning of World War II, and the number of reported cases for 1943 and 1944 was the largest ever reported for the entire country. The peak was reached in 1944 and the incidence of the disease has progressively declined since that time. Although these epidemic waves extend over wide areas, the attack rates in the different communities vary widely. In military experience (Sartwell and Smith, 1944), although there is a high

degree of correlation between the incidence of meningitis and the crowding together of recruits in their sleeping, living and travelling quarters, this is not the whole explanation; other factors play a role. For example, at times it has appeared that some correlation existed between the occurrence of cerebrospinal meningitis and high attack rates from respiratory diseases, such as influenza and measles, accompanied by coughing and increased nasal secretions leading to more abundant dissemination of the micrococci of the upper respiratory tract. The effect of such factors as fatigue and chilling in lowering resistance to the disease is still a matter of speculation.

**Prevention.** Before the modern era, epidemic cerebrospinal meningitis was a highly fatal and much dreaded disease. With the introduction of sulfonamide therapy in 1938, the whole outlook on the prevention of deaths and cases was changed. In the U. S. Army during World War II the case fatality rate was below 5 per cent. This low rate has not been achieved by any large civilian community because of delays in providing medical care, laboratory diagnosis and prompt institution of sulfonamide therapy. To the extent that this is overcome by public health measures, complications and deaths from this disease can be reduced to a minimum.

Reduction in the clinical attack rate has become a practical possibility under favorable circumstances. New cases arise from contact with carriers and only rarely from contact with another case. While isolation of patients is a desirable precaution, it can play only an insignificant role in the prevention or spread of the disease. Indeed, with the introduction of sulfonamide therapy, the meningococcus disappears very rapidly from the nasopharynx of a case and the convalescent carrier presents no problem. To reduce the frequency of cases it is necessary, therefore, to decrease the frequency with which the meningococcus is passed from one individual to another, i.e., to reduce the carrier rate.

In the past, efforts to achieve this have been practical only in the limited population groups of institutions, camps, and military establishments. Principal dependence was placed upon reducing the amount of crowding in living and sleeping quarters and recreational facilities so far as practicable. Sometimes carrier surveys were undertaken, and attempts were made to discover and isolate all of the individuals in a group who were harboring meningococci in the nasopharynx. This procedure has proved unsatisfactory for many reasons.

Discovery of the extreme sensitivity of meningococci to sulfadiazine provided an effective means of reducing the carrier rate. It has been demonstrated by Kuhns and others (1943) and Schoenbach and Phair (1944) that by the prophylactic administration of small doses (totalling two to six grams) of sulfadiazine to an individual in an affected group, over a period of several days, the carrier rate can be reduced practically to zero. Cheever (1945) reported that among 600,000 men to whom one-half to one gram of sulfadiazine was administered daily for a period of seven weeks, only five cases of meningitis were noted, three of which occurred within 24 hours of chemoprophylaxis. During the same period, 146 cases were observed among a smaller group of untreated individuals.

In civil practice, this procedure is useful in the protection of familial contacts or small groups of people who have been exposed to a case. The administration of a prophylactic dose or doses of sulfadiazine insures disappearance of meningococci from the throat and decreases the risk of a secondary case.

While the prophylactic administration of sulfadiazine is an effective procedure under appropriate circumstances, due caution should be observed in its use. It should be given under careful medical supervision. A small proportion of individuals, perhaps one in 200, are hypersensitive to sulfonamide drugs and may have reaction of varying intensity. Administration of small doses of sulfonamides to a large population group over a long time period may result in favoring the survival of a drug-resistant strain. It is better, therefore, to give the drug over a short period of time, i.e., two or three days, and repeat if necessary a week or two later. Chemoprophylaxis once terminated does not insure freedom from subsequent infection. Meningococci surviving in the nasopharynx of some individuals or introduced by new arrivals may again spread and the carrier rate reach a level as high or higher than that at the time the prophylaxis was begun. Nevertheless, the procedure has its sphere of usefulness in tiding over a period of emergency and has had sufficient trial to show that it is practical.

## TUBERCULOSIS

PHILIP E. SARTWELL, M.D., M.P.H.

Over the centuries, tuberculosis has been the foremost infectious disease as a cause of chronic disability and death in most parts of the world. Even today, when it is gradually coming under control in some countries, this is still true. The social and economic burdens which it creates are particularly devastating because its impact is heavily felt during the productive years of life, before the age at which cancer and heart disease make their greatest inroads.

Tuberculosis takes its greatest toll in regions with a low standard of living and among the underprivileged classes of the population. Although many other factors are involved, it is to some degree a barometer of social welfare; the downward trend in many countries has followed improvements in housing, nutrition, working conditions and the general standard of living of the masses.

One of the principal landmarks in the nineteenth century development of our scientific knowledge of tuberculosis was the work of Villemin, a French investigator, who in 1865 showed that the disease could be experimentally transmitted from animal to animal. Not only did this work indicate the transmissibility of tuberculosis, but it also demonstrated the unity of the disease in different hosts and of different clinical forms in the same host species. The concept of contagion, which in vague form can be traced far back in history, had gradually gained adherents despite the fact that in a chronic disease it is less easy to perceive than in epidemics of acute diseases. Two years after Villemin's work was published, William Budd, in England, assembled and described clearly many of the epidemiologic features of tuberculosis. He pronounced it to be a "true zymotic disease, of specific nature, in the same sense as typhoid fever, scarlet fever, typhus, syphilis, etc. . . . perpetuated solely by the law of continuous succession" and predicted that by disinfection of discharges containing specific morbid matter and by sanitary measures "we may, eventually . . . rid ourselves entirely of this fatal scourge." Budd had held these views for 10 years before he ventured to publish them. They are an illustration of the capacity of epidemiologic observations to lead to hypotheses later proved correct in the laboratory.

Koch's discovery of the tubercle bacillus (Koch, 1882) and his clear demonstration of its etiologic role was the most important single event in the whole scientific history of tuberculosis. Theobald Smith in 1898 differentiated the bovine from the human variety.

**Etiology.** The etiologic agent, *Mycobacterium tuberculosis*, is a nonsporebearing, acid-fast, rod-shaped micro-organism which can be cultivated on a considerable variety of artificial media, although growth is quite slow. It is pathogenic for most laboratory animals. There are several types, of which only the human and bovine types cause disease in man. The avian type is of agricultural importance because it produces disease in fowls and swine. The leprosy bacillus is a member of the same genus. A number of other species of acid-fast mycobacteria, most of which are saprophytic, have been identified. The differentiation of specific types of tubercle bacilli is largely based upon their relative capacity to induce disease in different species of laboratory animals.

Tubercle bacilli are destroyed by exposure to direct sunlight, by heat and by such disinfectants as phenol or tricresol solution. They are more resistant to chemical agents, especially acids and alkalis, and to antibacterial agents such as penicillin than are most pathogenic micro-organisms. They can remain viable for long periods in dried sputum. The concentration of chemicals and time of exposure to physical or chemical agents necessary for destruction of the bacteria depend on the nature of the secretions in which they are contained.

**Sources and Routes of Infection.** The principal source of infection is bacilli from the lungs and bronchi of persons with active pulmonary tuberculosis, contained in respiratory secretions that are coughed up and expectorated, or expelled in sneezing, talking or other respiratory effort. The organisms thus liberated into the environment may be directly inhaled in the form of droplets, or they may be reduced to droplet nuclei which remain suspended until inhaled (see Chapter 2); they may also become adherent to dust particles which are inhaled when stirred up. Wells, Lurie, and others have been able to infect rabbits by exposing them in chambers to aerosols of tubercle bacilli in suspension. Very small particles of the order of one micron diameter have the best chance of retention in the pulmonary alveoli, where they are most likely to initiate infection. Other possible mechanisms of infection are the contamination of the hands with bacilli-laden respiratory secretions and indirect transfer in this way to the mouth of the recipient, and contamination of food or eating utensils. The relative importance of these routes is not known, but such evidence as we have suggests that the inhalation of droplets or droplet nuclei deep into the respiratory passages is the chief mechanism. Drinking unpasteurized milk from tuberculous cows may initiate infection of the alimentary tract. Persons with extrapulmonary tuberculosis who are excreting tubercle bacilli, as in the urine or abscesses, but who do not have pulmonary lesions do not appear to be of any consequence as sources of infection. Infection may exceptionally be conveyed from tuberculous cows to stable workers (and the reverse is also possible).

The principal portal of entry of the tubercle bacillus is the respiratory tract. Primary lesions are most common in the peripheral portion of the lungs, indicating that the site of implantation is generally alveolar and that small inhaled droplet nuclei are likely vehicles for the organisms. The alimentary tract is a less important portal of entry; its relative importance will depend partly upon opportunities for ingestion of contaminated food. Primary lesions in the intestinal tract are rarely seen in the United States, but tuberculous mesenteric lymphadenitis is occasionally found. Tonsillar infection, with secondary cervical adenitis, may occur and very infrequently primary lesions in the skin or mucous membranes are observed.

**Pathogenesis.** The course of the disease is better understood in experimental animals than in man, and observation of its development in the guinea pig inoculated subcutaneously with virulent tubercle bacilli is instructive. After a latent period, an ulcer develops at the site of inoculation and tuberculin sensitivity appears, the regional lymph nodes become enlarged and caseous at the same time; later, disseminated tubercles appear and the animal dies. If a tuberculous guinea pig, infected several weeks previously, is again injected with tubercle bacilli, the local reaction is of a different character; it appears promptly, is severe and necrotic but circumscribed, and then heals (Koch phenomenon). The earlier infection, itself ultimately fatal, has altered the animal's response to subsequent reinfection.

In man, the sharp distinction once drawn between first infection and reinfection is no longer considered valid. Initial infection occurring in childhood is usually accompanied by gross enlargement of the regional lymph nodes (hilar nodes in the case of pulmonary infection) which may be roentgenographically visualized even when the primary focus is not visible, but this is not true of adults. Without knowledge of the individual's previous reaction to tuberculin, the initial infection cannot usually be distinguished from subsequent infection in adults. In the course of primary infection, bacilli are often borne in the blood or lymph stream to other organs in which tubercles develop. This post-primary dissemination occasionally gives rise to meningeal, miliary, renal or skeletal tuberculosis. Primary tuberculosis is frequently, however, a benign disease which heals spontaneously. Even in cases where roentgenograms reveal extensive pulmonary involvement, symptoms and signs are likely to be trivial or absent, especially in children. Occasionally, however, primary tuberculosis progresses to destructive pulmonary tuberculosis.

The pathogenesis of progressive pulmonary tuberculosis is poorly understood, especially in older persons. To what extent it results from reactivation of old primary lesions or foci resulting from post-primary dissemination (endogenous sources) and to what extent it is initiated by exogenous initial infection or superinfection has long been debated. As childhood infection becomes less frequent an increasing percentage of cases is probably attributable to recent infections. The initial appearance of tuberculous disease in a person past the age of 40, formerly considered unusual, is now observed not infrequently in the United States.

Pulmonary tuberculosis is a disease of highly variable character, ranging in severity from trivial infiltrates which never progress and are discovered only by accident, to virtual destruction of the lungs, and in speed of progression from extremely indolent lesions changing but little over many years to rapid development of pneumonic lesions. Progression may occur by direct spread or by way of the bronchi, blood or lymph stream.

Pleurisy with effusion is a common complication which may precede the appearance of roentgenographically visible parenchymal disease. In young adults at least, unexplained pleural effusions are likely to be of tuberculous etiology and are frequently followed within a year by pulmonary disease. Endobronchial tuberculous ulceration, which may lead to bronchial stenosis, is another common complication. In advanced disease, tuberculous laryngitis or enteritis may develop.

**Susceptibility and Resistance.** Once infection has taken place, the fate of the individual depends on a number of factors which are still poorly understood, and none of which can be quantitatively measured. Rich (1951) states that the extent and destructiveness of a tuberculous lesion depend upon the number and virulence of the bacilli that initiate the infection, the native and acquired resistance of the host, and the hypersensitivity of the host.

Lurie (1941) and Lurie and others (1955) showed by breeding experiments that in rabbits genetic constitution is a factor in native resistance. The resistant races are able more effectively to inhibit the growth of tubercle bacilli from the very beginning of infection. Kallman and Reisner (1943) demonstrated that when one of a pair of homozygous twins was tuberculous the co-twin was also tuberculous in most instances, while in the case of dizygotic twins or ordinary siblings the concordance was much lower. Puffer (1944) in family studies obtained suggestive

evidence of higher incidence among blood relatives of the tuberculous index case than among other household contacts. Thus, definite indications exist of hereditary factors in susceptibility.

Racial differences in susceptibility undoubtedly also exist. There is much evidence that Negroes are in general less resistant than white persons, although their higher mortality can partly be explained by environmental differences. Age at time of infection is an important factor; resistance is lower in infancy than at any other age, but the period from early childhood to the beginning of adolescence is one of relatively high resistance. Sex differences, though unimportant in childhood, are suggested by the more rapid rise of mortality after puberty in females and the later rise in males to a higher peak. The effect of pregnancy, apart from the burdens of caring for a family, is disputed.

There is good evidence that both silicosis and diabetes predispose to the development of active tuberculosis in the infected person. Influenza and measles probably have a similar, though temporary, effect.

It is very generally believed that many nonspecific factors such as nutritional deficiencies, fatigue, exposure to various kinds of environmental stress and perhaps emotional stresses as well have an adverse influence on resistance. We have, however, practically no scientific evidence bearing on their influence in man.

Thus, while exposure to the tubercle bacillus is one necessary factor for the development of tuberculosis, there are many poorly understood accessory factors which, taken together, determine whether the disease will develop in the exposed person and which might be thought of as etiologic in one sense. Osler's (1892) application of the biblical parable of the seed (the tubercle bacillus), the sower, and the soil (the host) is still apt. We have learned much about the seed but little about the biological characteristics of the host which determine the outcome of exposure. Tuberculosis is by no means unique among infectious diseases in this regard.

One of the most controversial issues in tuberculosis epidemiology has been the relation of tuberculin sensitivity to resistance. The importance of this question in relation to vaccination is obvious, since the only easily obtained measure of successful vaccination is the development of a positive tuberculin reaction. It is clear that the person who has been tuberculin positive for some time as a result of natural infection has already withstood successfully his primary infection, whether by reason of native resistance, age at infection, dosage of infection or for other reasons. It is also clear that whatever immunity may have been conferred by the initial infection is not very solid because active tuberculosis can develop at a later date in such persons. Comparisons between the incidence of tuberculosis in tuberculin-positive and tuberculin-negative groups are difficult to interpret for several reasons. Persons already infected have generally been more intensively exposed to tuberculosis in the past than uninfected persons and may still be subject to greater exposure. They may also differ with respect to socio-economic level, crowding and home hygiene. Those whose resistance was low have already been eliminated from the infected portion of the community by death or development of active tuberculosis. Furthermore, we must consider whether exogenous or endogenous sources of disease are more important; if the latter, the previously infected person would be at a disadvantage.

Students of nursing, whose environmental conditions are more or less similar during the years of training, have furnished the best data on this point. The findings of 21 comparative studies of nurses tuberculin positive or tuberculin negative on entry in training were summarized by Daniels (1944). Tuberculosis morbidity and mortality were generally higher in those who were negative at the beginning of training. The hazard of developing clinical disease was greatest during the first year after conversion of the tuberculin reaction, the degree of excess hazard depending on whether such minor manifestations of disease as erythema nodosum, pleurisy with effusion and uncomplicated primary complex were counted under morbidity. On the other hand, in community surveys certain workers, as for example Pope and others (1939), showed that subsequent tuberculosis morbidity and mortality were higher among children who were already tuberculin positive but free from clinical disease when they came under observation than among those still tuberculin negative. This may be explained by the environmental differences discussed above and by the likelihood that some of these children had been infected only recently.

Long (1950), in summarizing the development of current concepts on resistance, states that, in either native or acquired resistance, prompt localization of invading bacilli at the portal of entry is a significant element.

**Diagnosis.** Symptoms of pulmonary tuberculosis are variable, often insidious, and likely to appear late in the disease. They include fatigue, weight loss, fever and night sweats, cough, expectoration, chest pain (often pleuritic), hoarseness and occasionally hemoptysis. Physical signs are those of consolidation, excavation or pleural effusion; fine inspiratory rales may be the earliest sign. Local manifestations of extrapulmonary tuberculosis depend on the organs involved.

Accurate diagnosis rests on the triad of tuberculin testing, roentgenographic findings and bacteriologic study. Since these are of importance in both clinical study and public health programs, they will be discussed in some detail.

The first diagnostic procedure, the tuberculin test, has always been important in pediatric practice. It is also of increasing value in ruling out tuberculosis in adults with roentgenographic evidence of disease from whom tubercle bacilli cannot be recovered, since a large percentage of adults in many areas are now uninfected. In epidemiologic investigations the tuberculin test affords the only means of determining the prevalence of infection in a population.

Old Tuberculin (OT) is a glycerinized extract of heat-killed tubercle bacilli and their metabolic products, obtained from filtrates of fluid cultures. Seibert (1934) has developed a more refined product termed Purified Protein Derivative (PPD) which contains less nonspecific substances and is of greater uniformity. This product is gradually replacing OT in survey work. International standards of OT and PPD have been established. In recent years a common unit of potency, the Tuberculin Unit (TU), has been introduced. By definition, one TU is 0.00002 mg. International Standard PPD or 0.00001 ml. ("0.01 mg.") International Standard OT. It has been shown, however, that the two tuberculins are qualitatively as well as quantitatively different and that their relative potency varies from one dosage level to another.

Many technics of testing have been devised. The principal ones in use today are the quantitative intracutaneous (Mantoux) test employing graded dilutions of OT or PPD, the Vollmer patch test and the von Pirquet or scarification method.

The Mantoux has the greatest accuracy but the Pirquet is easy to perform and requires less equipment. The patch test is widely favored because of its ease of application and advantages for young children. However, it is somewhat inaccurate both because of the uncertainty as to whether the subject has kept the patch on for the required period and the greater difficulty of interpreting reactions; it is also more expensive.

Reactions are interpreted after 48 to 72 hours (in the case of the patch test the patch is removed at 48 hours and the reaction is read at 96 hours). With the Mantoux or Pirquet tests the transverse diameter of the area of induration should always be measured and recorded. The Mantoux test is usually considered positive when the reading is 5 mm. or more.

With the intracutaneous technics, 1 TU of either of the two tuberculins has often been used as a first dose in order to avoid troublesome reactions, followed in the case of nonreactors by larger doses, up to 100 TU of OT or 250 TU of PPD. However, the work of Palmer, Furcolow and others has demonstrated that many reactions elicited only by large doses of tuberculin are probably nonspecific and that such reactions show wide geographic variations in frequency. Therefore, the utility of doses greater than 10 TU is very doubtful. In the United States, a number of recent surveys have been carried out with the Mantoux test employing 0.0001 mg. of PPD (5 TU) as the only dose. For epidemiologic purposes, standardization and simplification of technics and dosage is obviously desirable. No tuberculin should be used that has not been compared in potency to that of the corresponding international standard.

The tuberculin reaction has high sensitivity for the detection of clinical tuberculosis. Few proven cases fail to react to 5 or 10 TU of either tuberculin. Sensitivity is depressed in critical illness, in measles and perhaps in pregnancy. How often persons positive to small or moderate doses of tuberculin lose their reactivity and revert to negative is unknown; this has been observed in infants treated with isoniazid but is probably infrequent in the general population.

The specificity of clear-cut reactions to small doses as an indication of previous or recent infection with tubercle bacilli is also high, although of course the reaction does not signify active disease. It becomes positive about four to six weeks after initial infection has taken place and before the appearance of clinical manifestations of disease. Thus, conversion of the reaction from negative to positive in an individual signifies that infection has taken place during the period between the last negative and first positive reactions or just prior to the last negative result. The first 6 to 12 months after conversion is a period when individuals should be closely observed for the development of tuberculous disease. Fluctuation in the intensity of the reaction in an individual has not been shown to have clinical significance.

The chest roentgenogram, properly performed and interpreted by skilled persons, provides a sensitive test of the presence or absence of pulmonary disease compatible with tuberculosis, and by serial films the progression or retrogression of established disease. As a screening procedure applied to contacts, suspects and supposedly healthy groups it has revolutionized case finding. Examination of large numbers of persons at minimal cost has been greatly facilitated by the development of photofluorographic equipment, with which the fluoroscopic image of the thorax

is photographed on a small film. This is supplemented by conventional roentgenograms in all cases in which it reveals positive or suspicious findings.

There are, however, limitations in roentgenography as a diagnostic tool which need to be appreciated. First, the roentgenologic appearance of tuberculous disease is not pathognomonic, and many other diseases can produce changes which require further study by other methods to distinguish reliably from tuberculosis. These include bacterial, viral and fungus infections of the lungs, malignancies, sarcoidosis and pneumoconiosis, among others. Second, the film reader's findings are subjective in nature and are much less accurate than was formerly supposed. This was first demonstrated in a study by Birkelo and others (1947) and has been amply confirmed. The same series of chest survey films, when read independently by several expert roentgenologists, or even when read several times by the same roentgenologist, will often reveal marked disparities in the cases classified as "tuberculosis" or "suspected tuberculosis." Recognition of this has suggested the practice of multiple readings of survey films, which will reduce the number of cases that are overlooked but at the same time will increase the number of persons erroneously called cases or suspects and placed under observation. The third limitation in roentgenography is that a single chest film cannot distinguish between active and inactive tuberculous disease in many cases. Other methods, coupled with repeated roentgenologic examinations at appropriate intervals, must be employed for this purpose.

Identification of tubercle bacilli in sputum or other secretions gives a specific diagnosis and a knowledge of the activity of the disease, thus complementing the information provided by roentgenogram. The simplest but least sensitive method is direct microscopic examination of a Ziehl-Nielsen stained smear of sputum. Culture of sputum or, if this cannot be obtained, of gastric washings, tracheal washings or laryngeal swabs is much more sensitive and should always be done if microscopic examination is negative. Since it is useful in distinguishing tubercle bacilli from saprophytes, it should be carried out in all cases if possible. Several examinations are often required before tubercle bacilli are found; hence, reliance should never be placed on a single negative report. Inoculation of material into guinea pigs remains the most reliable bacteriologic procedure because of its high sensitivity, its simplicity and its ability to distinguish pathogenic from nonpathogenic organisms.

**Classification.** The National Tuberculosis Association (1950) recommends a classification of pulmonary tuberculosis by extent into minimal, moderately advanced and far advanced stages, and by clinical activity into active, arrested and inactive categories. A definition of each stage and clinical category is provided. It should be understood that the classification by stage is purely anatomical and does not connote duration; thus, minimal disease may be early disease or may equally be of many years duration.

Other forms are classified according to the organ system involved. Table 1-10 is presented to indicate the relative importance as causes of death of the principal extrapulmonary forms in the United States at the present time. It is seen that pulmonary tuberculosis accounts for over 90 per cent of the fatalities, with meningeal and disseminated (miliary) tuberculosis responsible for most of the remainder.

**Therapy.** There have been three major developments in the treatment of tuberculosis: the sanatorium, collapse therapy and specific antibacterial drugs. These should be considered both from the viewpoint of their therapeutic value for the individual patient and their significance in relation to the public health.

Sanatorium treatment, introduced at the close of the nineteenth century, has three objectives: the provision of a hospital for closely supervised medical care; the indoctrination of patients in those living habits which offer the best chance for recovery and freedom from relapse; and the segregation of open cases to protect their families and the community against infection. Over the long period when no specific antituberculosis measures were available the sanatorium was the focus of the tuberculosis control program. A regime of carefully supervised rest, nursing, good food and medical supervision is still of major importance. The earliest sanatoria were privately operated, but public institutions rapidly took over the task. By 1955 there were indications that sufficient sanatorium beds were at last available in the United States, although they were not evenly distributed and many communities still had waiting lists. However, the construction and operation of sanatoria is one of the most expensive aspects of tuberculosis control, and in many countries whose economic resources are unequal to the burden, hospital facilities will be available for only a small fraction of the active cases for years to come.

Table 1-10. Number of deaths and death rates for tuberculosis by specified form, United States, 1952

(Exclusive of deaths among armed forces overseas. Rate per 100,000 estimated midyear population excluding armed forces overseas)

	Number of Deaths	Per Cent of Total	Death Rate
Tuberculosis—total of all forms	24,880	100.0	16.0
Tuberculosis of the respiratory system	22,745	91.4	14.6
Tuberculosis—total of other forms	2,135	8.6	1.4
Tuberculosis of the meninges and central nervous system	767	3.1	0.5
Tuberculosis of the intestines, peritoneum and mesenteric glands	150	0.6	0.1
Tuberculosis of the vertebral column	139	0.6	0.1
Tuberculosis of the bones and joints (except vertebral column)	63	0.3	*
Tuberculosis of the lymphatic system	39	0.2	*
Tuberculosis of the genito-urinary system	228	0.9	0.1
Tuberculosis of other organs	71	0.3	*
Disseminated tuberculosis	678	2.7	0.4

\* Less than 0.05.

Practically all infectious cases profit from a period of residence in a sanatorium. It has never been possible, however, to hospitalize all cases present in the community at a given time. Patients with limited involvement, in comfortable homes where there are no children, and able to take the necessary hygienic precautions may be allowed to remain at home. The necessary period of institutional treatment may be shortened by specific drug treatment; this is under study at present.

Rehabilitation work in the sanatorium and after discharge is playing an increasing role in the management of tuberculosis. Its object is to retrain the patient so

that he can when fully recovered take up an occupation suited to his physical limitations and thus reduce the likelihood of reactivation of disease. The social worker is also an important member of the sanatorium staff whose responsibility is to help the patient and his family solve the many problems, economic and social, which arise during this chronic illness.

A vexing problem has been created by the unwillingness of many patients to remain in sanatoria until considered medically ready for discharge. Others refuse sanatorium treatment altogether and some of these, because of their living habits, are a distinct hazard to their associates and to the public generally. Legally enforced segregation of these recalcitrants has been tried but has had limited use because of the fear of its adverse effect on the willingness of others to accept treatment.

In an earlier day, when the influence of climate on recovery was stressed, tuberculosis hospitals were constructed in out-of-the-way places. In recent years, the tendency has been to build them close to the population served (Chadwick and Pope, 1946). Among other advantages, this makes available the services of a better consulting staff. There has also been a trend toward treatment in general hospitals. With drug therapy, it appears that physicians in the community will assume much larger responsibility for the management of tuberculosis than was the case in the past quarter century when it was largely relegated to specialists in institutions. This necessitates greater attention to the clinical aspects of the disease both in medical schools and in postgraduate medical education.

Various methods have been used to collapse the diseased lung. The first was artificial pneumothorax, once used very extensively but now only occasionally. It has been partially replaced by pneumoperitoneum. Phrenic nerve interruption, thoracoplasty and extrapleural plombage are surgical measures which are of benefit in a certain number of cases. Recently, with the improvement in surgical technics, there has been a marked increase in surgical extirpation of diseased lung tissue by pneumonectomy, lobectomy or segmental resection. All of these procedures, employed in properly selected cases, are of value in rendering patients sputum negative and aiding in the arrest of the disease. They are adjuncts to proper general medical care.

Antimicrobial drug therapy, in the decade since it was introduced, has become the most important element in the medical management of tuberculosis. Methods of treatment are changing as knowledge increases, but the present position will be briefly summarized. Drug treatment is indicated in almost all instances of active tuberculosis of any organ, except perhaps in benign primary tuberculosis in older children. Isoniazid and streptomycin are the most effective drugs, administered together or with para-aminosalicylic acid. Several other promising agents are under study. Drug therapy must be continued for at least one year and often longer. Each of these drugs can occasionally produce toxic effects necessitating a change in the regimen. The development of drug-resistant strains of tubercle bacilli in patients under treatment is not uncommon and may be detected by *in vitro* sensitivity tests, although the correlation between results of such tests and clinical response is not perfect. Drug treatment may, if delay in hospitalization is unavoidable, be commenced before admission to hospital. In persons known to have been recently infected as indicated by tuberculin conversion, especially children, prophylactic

chemotherapy has been proposed but is not yet widely recommended, pending the outcome of current controlled studies.

There is no doubt that antibacterial drugs have radically improved the previous hopeless prognosis in miliary and meningeal tuberculosis, nor that they have greatly lengthened survivorship in pulmonary and other forms. There has not been time for measurement of the ultimate prognosis in pulmonary tuberculosis treated with these drugs. Along with the clinical improvement, sputum conversion in pulmonary tuberculosis is usual, but relapse can take place and patients whose disease has become inactive cannot be regarded as cured in either a bacteriological or clinical sense. Early discovery of active tuberculosis and close supervision of recovered cases remain essential, as do other well-established elements in treatment (rest and adjunct surgical treatment).

**Frequency of Infection.** Tuberculin testing of population groups has been done for many years on a wide scale, yet differences in technics and in the selection of subjects and the dearth of long-term programs have restricted the comparative knowledge gleaned from them. Certain general statements may be made, however. The percentage of reactors rises steadily with age to adulthood but may show a slight decline after the age of 50 or 60. The age curves are similar for males and females in childhood but may be somewhat higher for males in adult life. In families where there is an open case of tuberculosis, the rise is much faster. In crowded environments and areas where the tuberculosis death rate is excessive the rise is more rapid than in rural communities. Evidence of an occupational hazard is afforded by the fact that students of nursing and medicine in some situations have shown a higher risk of infection than other groups.

There has unquestionably been a sharp drop in the prevalence of infection in the United States in recent years. Thus, while past surveys not infrequently revealed 30 per cent or more of young adults reacting, Canada and Babione (1950) found that fewer than 10 per cent of young adult males entering the Navy in 1948 were positive to 5 TU of PPD. A marked drop has been observed in the number of reactors among students entering colleges.

Information on the tuberculin status of older adults is much less abundant. A community-wide program was conducted by Comstock in 1950 in Muscogee County, Georgia, employing a single test of 5 TU PPD. His findings on residents of the urban area of the county are presented in Figure 1-11.

The BCG program conducted by the International Tuberculosis Campaign (1951), a partnership of UNICEF and three Scandinavian volunteer organizations with guidance from WHO, has provided valuable information on the prevalence of infection in many other countries. Children from ages 1 to 18 were tested, usually with 5 or 10 TU of PPD (in some countries the Moro test was used for children under 12). Countries of Eastern Europe, North Africa, the Middle East, Asia and Latin America participated. In most places as many as 50 per cent of children were infected by age 15, the number being higher in the cities than in rural areas.

**Prevalence and Incidence of Pulmonary Tuberculosis.** This may be measured either by the rate of discovery and reporting of new cases or by the results of mass roentgenographic surveys. Each method has serious defects for comparative purposes. The first is dependent upon the activity of case-finding programs and the

Fig. 1-11. Percentage of persons in Columbus, Georgia, who reacted to 0.0001 mg. PPD. in 1950, by age, race and sex. NM, Negro male. NF, Negro female. WM, white male. WF, white female.

Fig. 1-12. Prevalence of tuberculosis per 100 persons examined in 1946 photofluorographic survey, Muscogee County, Georgia. Height of bar: persons "to be followed" on basis of 1946 films. Shaded portion: cases found bacteriologically positive in 6 years' observation.

practice with regard to reporting of cases, and results of the second depend on what population groups are selected for examination, as well as the diagnostic criteria employed. The incidence rate as measured by reported cases in most sections of the United States showed a slight to moderate rise during and immediately after World War II when mass surveys were introduced on a very wide scale but has since declined slowly but progressively. Bed occupancy has also declined a little in the past few years; this decline is probably due both to the falling incidence of disease and to improved therapy which has shortened the period of hospitalization.

While mass surveys are not suitable for comparison of prevalence in different places or for studying time trends, they do give a useful picture of the relative prevalence by age, sex and race. The community survey in Muscogee County,

Fig. 1-13. Discovered incidence of new cases of tuberculosis among persons with negative photofluorograms in 1946, in subsequent 5 years, Muscogee County, Georgia. Rates per 1,000 population per 5 years. Height of bar: total confirmed and suspect cases. Shaded portion: bacteriologically positive cases.

Georgia (Comstock and Sartwell, 1955), revealed that total prevalence increased markedly with age but that a much larger proportion of cases in the younger persons were active. Comparison between white and Negro prevalence showed a somewhat higher total prevalence in whites, but again a larger proportion of discovered Negro cases was active (Fig. 1-12). The incidence of new cases in a 5-year period after the survey, among the population who were negative by roentgenogram at the time of survey, was higher in Negroes and especially in those under 45 (Fig. 1-13). The fact that Negroes have a higher incidence and yet a lower prevalence of tuberculosis than white persons is an apparent paradox; it is explained by the greater likelihood that the white person will survive his infection and subsequently be discovered as an inactive case.

**Mortality.** Until recently, the mortality rate provided the best single measure of the magnitude of the tuberculosis problem in a community and of time trends, for those countries where causes of death were determined with reasonable accuracy. There are still, however, many areas in the world where, because of lack of medical services and the consequent inaccurate certification of causes of death, the mortality rate cannot even be estimated. Furthermore, since the advent of

Fig. 1-14. Mortality rates for all forms of tuberculosis, per 100,000 population (logarithmic scale).

effective drug therapy mortality rates can no longer be looked upon as reflecting directly the trend of morbidity.

Although the records are fragmentary and unreliable, there are indications that tuberculosis mortality was on the increase in the early part of the nineteenth century in Europe and reached its highest levels during the period of industrial revolution. Since reliable rates have become available, however, the trend of mortality in the United States, Great Britain and most of the Commonwealth nations, and several European countries has been steadily downward for many years, being interrupted only by wars and economic depressions when these had serious effects

on civilian life. Over the past quarter century in the United States, this trend has been most rapid for infants and for the more acute forms of the disease (miliary and meningeal) often seen in infancy. From 1900 to 1916 the rate of decline was about 2 per cent per year; after a brief rise, coincident with World War I and the 1918 influenza pandemic, the decline was resumed at an accelerated rate, about 4 per cent per year. Beginning about 1948, the downward trend has been sharply accelerated, and there is little doubt that this was due chiefly to the introduction of specific drug therapy, although a change in the method of classifying causes of death was also made at that time.

Figure 1-14 shows the rates from 1900 in the United States contrasted with Bavaria and Chile, the rate scale being logarithmic. It will be noted that the trend in Bavaria has generally paralleled closely that in the United States but that there have been three major interruptions occasioned by World War I, the economically disastrous inflation of 1922-23, and World War II. Of these, the rise in World War II was the most serious, while in the United States, where the war had much less effect on civilian populations, there was little change in the trend. Rates for Chile are included to show one of the countries where mortality remained high over a long period but has recently dropped sharply. It has been suggested that the rapidly increasing industrialization of Chile was responsible for the sustained high rates.

Along with the downward trend, a shift in age distribution of mortality has occurred, especially among males. This is illustrated by data for England and Wales for three periods (Fig. 1-15). The decline in young adult life has been much greater than for older persons. This observation seems to indicate that an individual now encounters his greatest risk of death from tuberculosis at an advanced age in contrast to the experience some years ago. However, Frost (1939) pointed out that if viewed in the light of prior experience of the cohorts comprising each age group, a different conclusion might be reached. The cohorts now experiencing the highest mortality rates are those who in earlier life had still higher mortality. Analysis of mortality in Massachusetts on this cohort basis shows that each cohort observed through most of the life span of its members has experienced its highest mortality in infancy and its next highest in the third decade of life, the rates declining thereafter. This suggests that survival through a period when tuberculosis mortality was high implies a continued excess risk of dying from tuberculosis, owing perhaps to the delayed effects of earlier infection.

There has also been a marked change in the relative mortality of males and females, consequent on the faster downward trend of female rates. In 1900, males in the United States had the lower mortality rate, while in 1954 the male rate was more than twice as high as the female. We have no satisfactory explanation for this shift.

Some countries (e.g., Japan) did not share in the decline in mortality prior to 1945 but in most of these it is now going down rapidly. Others, mostly in underdeveloped parts of Asia, Africa and South America, whose mortality records are too inaccurate for the visualization of trends, still are known to have a continuing high toll of death.

In the United States, tuberculosis mortality is much higher in Negroes than in whites and is also high in the Spanish-American population of our southwestern states. Wolff (1940), in studies of mortality in different countries, found that

Fig. 1-15. Mortality from all forms of tuberculosis, England and Wales, by sex and age in 1911, 1931 and 1951. Annual rates per 100,000 population.

industrialized nations in general had lower mortality rates than predominantly agricultural ones, a difference which he attributed to the higher standard of living in the former. Within the United States, on the other hand, he found positive correlation between mortality rates of states and their index of industrialization.

Studying the effect of economic status on tuberculosis mortality by age and sex, Terris (1948) divided the population of Buffalo, New York, into economic quarters, using four indices. He found that the difference in mortality by economic level was small for females and young males, but there was a great difference for males over 30 years of age, mortality declining as economic status improved. Terris suggests that conditions of occupation, in addition to economic status per se, are responsible for this effect. It has been amply demonstrated that mortality varies with occupational class, being lowest in the professional groups and highest in unskilled workers.

**Familial Spread.** The enhanced risk of tuberculosis in families where one member is already suffering from the disease has been appreciated for many years. It required planned long-term observations, however, to document this and to demonstrate the degree of excess risk. Such studies were done by Downes (1935), Brailey (1940) and Puffer and others (1952). The life-table method of analysis of data suggested by Frost (1933) has been helpful in contrasting the experience of tuberculous households with control households or the general population. Prevalence of tuberculosis in household contacts of "index cases" at the time of their initial examination is considerably higher than in the general population. Periodic examination of such household contacts has revealed a continuing excess incidence of new cases over a period of years. Their frequency of infection as revealed by tuberculin testing is also much higher than in the rest of the community (McPhedran and Opie, 1935). As would be expected, contacts of positive or advanced cases sustain higher risks of infection, disease and death than contacts of sputum-negative cases. These risks also vary according to age, sex and race; the age at which exposure took place; and presumably the duration and intensity of exposure.

**Vaccination.** Almost from the discovery of the tubercle bacillus, efforts have been made to develop an immunizing agent, although, since the immunity provided by natural infection is indecisive, the hope for an effective vaccine was not very great. Many types of vaccine have been tried on experimental animals, and at least three—killed virulent bacilli, living attenuated strains and living vole bacilli—in man. Out of this work there has emerged one agent, BCG, which today is used over the world but about which dispute still centers.

BCG (bacillus Calmette-Guérin) vaccine is composed of living bovine type tubercle bacilli which have undergone attenuation until they are no longer capable of inducing progressive tuberculosis. In the course of prolonged subculturing on a medium containing ox bile, this strain was found to have lost most of its virulence (Calmette, 1928). It was originally employed in France as an oral vaccine administered to newborn infants. A considerable proportion of such infants became tuberculin positive but for a long while no adequate test of its efficacy in preventing tuberculosis was undertaken.

Heimbeck (1932) in 1927 undertook the subcutaneous vaccination of tuberculin-negative student nurses in Oslo and found a much lower incidence of tuber-

culosis among the vaccinated nurses than among those who declined immunization. Following this promising work its use became more widespread, especially in Scandinavia, and further evaluation was undertaken. In the United States, Rosenthal and others (1945) vaccinated children in tuberculous households; Park, and later Levine and Sackett (1946), carried out a similar project in New York; and Aronson and his associates (1952) vaccinated Indian children. In Canada, Ferguson and Simes (1949) also vaccinated Indian children. All of these studies included controls, i.e., unvaccinated children so selected as to be thought to have a similar tuberculosis risk, although in some of them the controls may be criticized as being selected by less than ideal methods. Each of the cited investigations, with the exception of that by Levine and Sackett, produced evidence that vaccinated children were protected to some degree, though not completely.

The study by Aronson is perhaps the most impressive because of the long observation period and the large number of subjects. There were 1,551 vaccinated children and 1,457 tuberculin-negative controls among 8 tribes living in 5 areas of the United States and Alaska. They were kept under periodic observation, with some lapses, for a period of 13 to 15 years, at the end of which time there had occurred 12 deaths from tuberculosis among the vaccinated and 65 among the controls; deaths from other causes were about equally distributed between the two groups. Similar results prevailed in the Canadian study, which was smaller but in which the selection of controls was perhaps more satisfactory.

In Denmark, the accidental infection of a number of school children by a tuberculous schoolteacher (Hyge, 1949) furnished an indication of the efficacy of vaccination, since a portion of the class had been recently vaccinated and others were still tuberculin negative. In Sweden (Dahlstrom and Difs, 1951), data on the incidence of tuberculosis in vaccinated soldiers contrasted with others who refused vaccination pointed in the same direction. Neither observation is wholly convincing but they support the conclusions drawn from all but one of the controlled studies, that a moderate degree of protection is conferred.

Most of the work cited was done under somewhat special circumstances: the subjects were children, the risk of tuberculosis was high, and the observation periods after vaccination were rather brief. Nevertheless, within the limits of the experiments, the evidence is rather impressive.

In programs of tuberculosis control, not designed to provide scientific evidence of the value of BCG, many millions of people in many parts of the world have been vaccinated, largely since World War II. This experience has at least provided evidence of the general harmlessness of BCG, for only two fatalities reasonably attributable to the vaccine have been reported. In these cases it seems fairly clear that the organisms which produced progressive disease and death had not regained their virulence, since the tubercle bacilli recovered from the lesions were no different in their cultural characteristics or pathogenicity for experimental animals from typical BCG strains. The explanation probably lies in a peculiar absence of resistance in these particular subjects. It has also been observed in experiments on guinea pigs in which silicosis has been artificially produced that subcutaneous BCG infection seemed capable of inducing progressive pulmonary disease (Vorwald and others, 1954).

Various special problems complicate the preparation, distribution and adminis-

tration of BCG and necessitate careful and intelligent planning and supervision. The vaccine must be standardized both as to numbers of viable organisms and their degree of attenuation; it must be refrigerated and used within a two-week period in order to insure viability, except where freeze-dried preparations are used; bacteriological safety testing also presents difficulties where the interval from manufacture to use is so short. Vigilance is required to avoid contamination of cultures with virulent tubercle bacilli.

Current practice in vaccination is to first do a tuberculin test and limit vaccination to those negative to 10 TU of tuberculin, except that prior testing is unnecessary in newborn infants. Vaccine is administered in the deltoid region by the intracutaneous or multiple puncture technic, 0.1 ml. being used if the intracutaneous method is chosen. Over a period of several weeks a small nodule or ulcer develops at the site and slowly heals in the course of a few more weeks. Occasionally, some enlargement of the axillary lymph nodes appears but this usually subsides without intervention. On retesting after six to eight weeks the reaction is usually positive, although the degree of hypersensitivity is not great. Over 90 per cent of conversions can be obtained under favorable circumstances. Sensitivity tends to wane markedly with the passage of time and the question of whether to revaccinate those who have reverted has not been answered.

Opinions of authorities on the usefulness of vaccination range all the way from strong (and sometimes uncritical) enthusiasm to equally strong condemnation. Opponents point to the fact that tuberculosis mortality has fallen as rapidly in some regions where it has not been used as in any where it has. They are skeptical of the ability of an agent generally administered in childhood, the effect of which in inducing tuberculin hypersensitivity is impermanent, to affect materially the mortality in older persons who now experience the highest death rates.

Much of the argument centers about the indications for vaccination. It has been pointed out (Palmer and Shaw, 1953) that in four areas where BCG was applied on a large scale the effect in the next few years was very small because a great majority of new cases and deaths occurred among those already infected prior to the vaccination program and hence ineligible for vaccination, rather than among either the vaccinated or unvaccinated nonreactors. The prevailing opinion at present seems to be that in the United States general vaccination is not advisable but vaccination of persons with special risk is desirable; these may include students of medicine and nursing, persons in household contact with tuberculosis who are still tuberculin negative and infants in high-risk groups as, for example, Negroes in communities with a high Negro mortality. On the other hand, in countries where economic resources simply do not permit the use of other control measures such as segregation of active cases in hospitals, BCG has been employed on a wholesale scale since the end of World War II. These are in general the countries where tuberculosis mortality is still high and where nearly everyone will be exposed to natural infection during his lifetime, in contrast to those areas where it appears likely that only a minority will be so exposed.

**Control.** The elements in a sound control program will be based on all that is known of the clinical aspects, bacteriology, pathogenesis and epidemiology of the disease.

Perhaps the surest way to reduce tuberculosis is through general improvement

in the economic and social welfare of the community. While this is beyond the specific responsibilities of the physician and health officer, they can throw their influence into the demand for better living conditions. Substandard housing, with its attendant crowding of families, deficiency of sunlight, poor ventilation, lack of facilities for cleanliness and lack of recreational opportunities is a potent factor which can be attacked through slum clearance and the substitution of good dwellings subsidized by government if necessary. In the field of industrial hygiene, good working conditions, the limitation of working hours and the provision of adequate pay are important. Much can be done toward improving the nutrition of the community. Adequate assistance to the needy is essential.

Specific measures aimed at the control of tuberculosis are those which will enhance specific resistance, foster early diagnosis, prevent spread of infection and provide effective treatment and rehabilitation of patients. These activities are the responsibility of the physician, official public health agencies and the voluntary tuberculosis associations working in close and friendly cooperation and, in a larger sense, of the whole community.

Early diagnosis involves all of the agencies listed above. It begins with alertness on the part of the physician to this disease and knowledge of its clinical character. Provision of clinical roentgenographic and bacteriologic facilities is an essential responsibility of the health department.

It is not enough to diagnose properly the suspects who present themselves to the physician. Certain groups in which the prevalence of tuberculosis is known to be high must be systematically searched for unsuspected cases. Of these, the most important are the persons exposed within the family to known cases of tuberculosis, all of whom should be examined at least roentgenographically. The detailed methods of examination and frequency of repetition of such examinations will depend on the contact's age, the status of the family and various clinical or epidemiologic factors. Mass case-finding methods should not lead to the neglect of contact examinations, which have always been the most efficient means of case finding in terms of number of cases discovered per unit of persons examined. Such cases may represent either persons infected by the already known case or hitherto undiscovered sources of infection.

Surveys, by means of roentgenograms, tuberculin tests and bacteriologic methods, of population groups in which there is evidence for an excessive incidence of tuberculosis may be indicated. Such groups include operatives in some industries, inmates of institutions (especially mental hospitals and prisons) and relief recipients. Routine roentgenographic examination of all patients admitted to hospitals for illnesses other than recognized tuberculosis has been shown to be a fruitful method of case finding. There are other population groups as, for example, school-teachers, who should be routinely x-rayed annually because of the public health importance of finding tuberculosis among them. A roentgenogram should be a routine part of the prenatal examination since it is in infancy that the most urgent necessity of protection against exposure exists. Both factors (excess incidence and hazard to the public) are indications for the annual examination of nurses and other personnel involved in medical care. Roentgenograms should be routinely taken of military recruits and, where possible, of applicants for industrial employment.

For groups at special risk, an effective means of medical supervision from the standpoint of tuberculosis diagnosis and control is to do routine periodic tuberculin tests on nonreactors. In this way, conversion can be detected and the converters closely observed by roentgenographic and other methods for the development of early disease. Detection and observation of converters is now widely applied in medical and nursing schools and has even been tried on a community-wide basis (Gedde-Dahl, 1948). Among younger school children, testing programs with roentgenographic observation of positives and converters and with intensive search for household sources of infection has been tried with varying success; Wood and Mantz (1954) suggest that it may be a productive case-finding method.

For the general population, the value of mass roentgenographic surveys is fairly well established. They bring to light considerable numbers of unreported cases. While many of these are not of clinical importance, this method gives the best opportunity to discover active minimal disease at a stage where prospects of arrest and rehabilitation are brightest. A rise in the reported percentage of minimal cases, coinciding with the wide introduction of this procedure, has been noted. The "yield" of active cases from surveys has averaged a little under 1 per 1,000 persons examined. Mass surveys may be useful in stimulating public support for other elements in a tuberculosis control program such as provision of sanatorium beds, and they have educational value. To be effective, they must be properly planned, preceded by an educational campaign and followed by competent, long-continued medical observation and treatment of the discovered cases and suspects. Many surveys have failed in these respects. Disadvantages of mass surveys are their expense, their failure to reach the entire population, and the possible creation of a sense of false security among individuals receiving negative reports. It should be emphasized that mass surveys are only one component of a tuberculosis control program.

Once a diagnosis of tuberculosis has been made, every case should be promptly reported to the health department, whose responsibility it is to keep an up-to-date register of all known cases in the community. Without such records it is obviously impossible for the health department to furnish assistance in securing hospitalization, follow-up of the case and examination of contacts. Furthermore, complete reporting is essential, regardless of the individual patient's need for health department services, in order to assess the extent of the problem and the adequacy of community facilities for control. The public health nurse has an important role, through periodic visits to the patient's home, of educating the patient and his family concerning the disease and precautions to avoid transmission of infection; arranging for and encouraging examination of contacts; and arranging for hospital admission. She may also carry out tuberculin tests, collect sputum for examination and bring to the attention of the physician and of social agencies economic and social problems of the family.

Since silicosis predisposes to tuberculosis, excessive inhalation of silica dust in such occupations as quarrying and foundry work should be avoided through proper industrial hygiene practices. While this hazard has been greatly reduced in the United States, men who have sustained exposure over a period of years should be roentgenographically examined. Diabetics should also receive such examinations.

One of the major achievements in preventive medicine in the United States has

been the control of bovine tuberculosis. This has resulted from two measures: the pasteurization of milk supplies and the removal of tuberculous milch cows by a nationwide program of tuberculin testing of herds, with slaughter of infected animals. The latter measure has reduced the reactors to a fraction of 1 per cent. Extrapulmonary lesions in the human population, particularly cervical and mesenteric lymphadenitis, which were once common, have declined more rapidly than pulmonary tuberculosis. These types of disease are considered on the basis of bacteriologic studies to be frequently the result of infection with bovine tubercle bacilli, presumably via ingestion of infected milk.

Despite the success of the campaign, it is evident that tuberculosis in cattle has in no sense been eradicated or permanently brought under control. It is as capable as ever of spreading rapidly through herds and can be kept down only through constant maintenance of the program of testing and removal of reactors. The cost to the farmer and to government of this program is large. In some countries where such a program is not in effect, where pasteurization is limited to larger dairies and where the public is not accustomed to boil milk human tuberculosis of bovine origin is still important.

Segregation and treatment of patients in sanatoria and the role of specific drugs have been discussed under therapy. A separate section is devoted to vaccination.

**The Outlook.** Long before World War II, it was predicted (Frost, 1937) that tuberculosis would be ultimately eradicated in this country, barring major disaster. The war brought temporary disaster, and in countries whose civilian populations suffered heavily a marked rise in mortality occurred promptly. Immediately after the war, however, the downward trend was resumed and has been accelerated since the introduction of specific drugs. There is no room for complacency for it has been repeatedly pointed out that morbidity has not declined nearly as rapidly and that there remain large numbers of unknown active cases in the population. Nevertheless, if the vigor of our efforts is not permitted to wane the outlook appears bright for control in the near future, to a point where for the first time in the history of western civilization tuberculosis will be an insignificant problem.

## AIR-BORNE INFECTION

ALEXANDER D. LANGMUIR, M.D., M.P.H.

### MODES OF TRANSMISSION OF RESPIRATORY DISEASES

**Introduction.** Air-borne infection and contact infection have long competed for scientific favor as the predominant mode of spread of respiratory diseases. The pendulum of interest, first in one and then in the other, has swung sometimes to extremes. It is yet to be stabilized.

Air-borne infection is an established reality in the laboratory, both in experimental animals and in human subjects. It is now well recognized as a serious hazard to laboratory workers. It is clearly important in the pulmonary mycoses and probably in pulmonary tuberculosis. It apparently plays some role in the occurrence of certain residual cross infections in pediatric and contagious disease wards when isolation precautions to prevent contact spread are rigidly maintained. The severe epidemics of respiratory disease and streptococcal infections that occur among military recruits may be partly air-borne. With respect to the common cold, influenza and the common respiratory diseases that afflict the general population, there are almost no data to determine which mode of spread is dominant but the weight of scientific opinion presently favors contact infection.

Exact delineation of the relative importance of these two modes of spread and the conditions under which one or the other may occur is essential to the development of sound control practices since the approaches to the two problems are quite different. The prevention of air-borne infection is a problem for the environmental engineer, while the prevention of contact infection is a problem for the health officer, the public health nurse and the health educator. The former is amenable to the mass approach, utilizing the principles of air sanitation; the latter is an individual problem of personal hygiene.

The increasing interest in air as a possible vehicle of infection has resulted in a large scientific literature dealing with such problems as methods of sampling air (Bourdillon and others, 1948); the characteristics of infectious particulate aerosols (Rosebury, 1947; Bourdillon and others, 1948); the penetration and filtration of particles in the respiratory tract (Brown and others, 1950); and methods for both natural and artificial contamination of the air (Rosebury, 1947; Bourdillon and others, 1948). Numerous techniques have been developed for controlling infectious micro-organisms in the air, such as ventilation, ultraviolet irradiation, disinfectant vapors and dust suppression (Subcommittee for the Evaluation of Methods to Control Air-borne Infections, 1947; Subcommittee on Air Sanitation, 1950). While

the science of air-borne infection has yet to provide a solution to the control and prevention of the respiratory diseases in the general population, some practical applications of limited scope have been developed.

Probably more important is the accumulated knowledge regarding mechanisms of respiratory tract infection. This is basic to whatever control measures are eventually developed. Furthermore, it is basic to one phase of the military science of biological warfare, the potentialities of which only the future can determine.

**Definitions.** Much confusion and some controversy have arisen through the use of unnecessarily vague and ill-defined terms. It is common to hear the term "the air-borne infections" applied loosely to the acute respiratory and contagious diseases, although these are known to be spread, in many circumstances, by contact. Pulmonary tuberculosis is usually referred to as a "contact" disease, although increasing evidence is accumulating that it may be primarily an air-borne infection.

The portal of entry of the infectious agent is usually accepted as "the respiratory tract" without distinguishing the exact locus where the agent first invades the tissues. The manner of exit of infectious material from the patient is usually stated to be "the respiratory secretion" without clear distinctions between saliva, sputum or nasal discharges.

To avoid confusion and to provide for as orderly and as precise a discussion of the subject as possible, the following definitions are offered:

*Respiratory infections* include those infectious diseases in which the primary pathological process is in the respiratory tract and, in addition, those systemic diseases in which the portal of entry is through the respiratory tract.\*

*Portal of entry* is the exact locus where the infectious agent first invades the tissues, which may be anywhere from the nasal mucous membrane down to the alveoli.

*Routes of transfer* include four different mechanisms:

1. *Contact*, transmission directly, as in kissing, or indirectly by contaminated hands, toys, surgical instruments, or other material objects.
2. *Droplets*, transmission directly by projection onto the conjunctivae and the face, or into the nose and mouth.
3. *Droplet nuclei*, transmission indirectly by inhalation of the small residues which result from evaporation of droplets and which remain suspended in air of enclosed spaces for long periods of time.
4. *Dust*, transmission indirectly by inhalation or settling of larger particles which arise from secondary reservoirs of infection on floors, clothes or bedding and which remain suspended in air for short periods of time.

While a precise distinction between these four routes of transfer may not always be possible, each constitutes a different mechanism for which different control procedures must be designed.

Most confusion has arisen over whether droplet infection should be considered a form of air-borne infection or a form of contact. In a limited sense, droplets actually travel a short distance through the air, but in a broader sense they succeed in

\* Another group of infections which may be spread either by the contact or the air-borne routes are the surgical wound infections. These are discussed only casually in this chapter.

transmitting infection only between persons in close association. Furthermore, none of the engineering devices of aerial disinfection or dust suspension has any appreciable effect on droplets. The control of droplet infection depends on the promotion of personal hygiene and individual protection as with the control of contact. Therefore, from a practical and realistic point of view, *contact infection* will be defined to include droplet infection, and *air-borne infection* will be restricted to transmission by droplet nuclei and dust.

**History of Changing Concepts: Air-Borne vs. Contact Infection.** The history of the competition between contact and air-borne theories for scientific favor may be roughly summarized in five periods:

<u>Period</u>	<u>Approximate dates</u>	<u>Attitude toward air-borne infection</u>	<u>Predominant ideas</u>
1	Prior to c. 1890	Popular	Miasma and malaria
2	c. 1890 to c. 1934	Apathy	Contact and droplet infection
3	c. 1934 to c. 1945	Expectation	Droplet nuclei and dust infection
4	c. 1945 to c. 1950	Disappointment	Failure of practical applications
5	Since c. 1950	Guarded concern	Tuberculosis, laboratory infections, biological warfare

**FIRST PERIOD.** From earliest times to the end of the nineteenth century air was popularly conceded a most important role in the occurrence of epidemics. The concept of miasma (noxious vapor) and malaria (bad air) imply air-borne infection. These were applied indiscriminately to respiratory, enteric and arthropod-borne diseases alike. As distinguished an epidemiologist as William Farr ascribed the great epidemic of cholera in London in 1849 to miasmata diffusing from the Thames River (Farr, 1885). He demonstrated a remarkable correlation between cholera mortality and elevation above Trinity high water mark to support his contention.

**SECOND PERIOD.** With the advent of bacteriology, early findings first supported the air-borne theory, but with later findings general scientific opinion swung progressively toward a predominant interest in contact and droplet infection. Following Pasteur's early demonstration of bacteria in air, Lister introduced carbolic acid sprays into his operating room on the assumption that air was the chief cause of surgical sepsis. It was soon found, however, that with strict aseptic technics, the corrosive aerial sprays were unnecessary. Thus, the spectacular results of aseptic surgery disproved Lister's assumption and established the pre-eminent importance of contact in wound infections.

These aseptic technics were soon applied, first in Europe (Chapin, 1912) and then in the United States, to the care of patients with acute contagious diseases. The immediate success of the use of cubicles and strict isolation precautions in the care of such patients made possible the transformation of pesthouses to modern isolation hospitals and permitted the rapid development of hospital pediatrics. The conclusion that contact was the dominant mode of spread of acute contagious diseases was unavoidable.

These dramatic discoveries overshadowed the careful studies of the bacterial contamination of the air which were proceeding concurrently. Fluegge in Germany, and many others in Europe and the United States showed that certain pathogenic bacteria could be recovered from the air and the dust of inhabited places. Tubercle

bacilli were recovered regularly when culture plates or animals were exposed within a few feet to the direct coughing of tuberculous patients. Pus-forming organisms were isolated from surgical wards and even from operating rooms. After the contamination of the mouth with *B. prodigiosus* (*S. marcescens*), the organism could be recovered from the far corners of a large room or even shown to travel on air currents down corridors and up two flights of stairs. It was believed, however, that most pathogenic bacteria either rapidly died or lost their virulence when exposed to air. Furthermore, the concentration of pathogens recovered from air, except within the range that moist droplets of saliva or mucus could travel from the mouth, was exceedingly low. The weight of scientific opinion, including such workers as Fluegge, swung strongly away from air-borne infection toward the importance of contact and droplets (Chapin, 1916).

A great leader of the trend was Dr. Charles V. Chapin, Superintendent of Health, Providence, Rhode Island, from 1884 to 1931. He studied the cases of communicable diseases occurring within his jurisdiction. He showed that they were concentrated among families, but only rarely spread to adjoining families in the same or neighboring houses. From this he concluded that contact must be much more important than air-borne infection. He followed closely the rapidly expanding scientific literature in Europe and in this country and in 1910 wrote a critical treatise "Sources and Modes of Infection" in which he summarized the available evidence and argued that the force of the epidemiological evidence strongly supported contact and droplet infection as dominant for most respiratory infections. Chapin, however, specifically excepted pulmonary tuberculosis in which he admitted that air-borne infection might be important.

Through his writings and leadership in the American Public Health Association he discouraged terminal fumigation, then a popular practice, and instead he promoted good personal hygiene and simple isolation technics. He built in Providence the first modern isolation hospital in this country and established a pattern which was copied on a national scale. His persuasive logic dominated epidemiological thought and general public health practice in the field of communicable disease control in the whole United States. His influence is still felt strongly today.

THIRD PERIOD. For a quarter of a century from 1910 to 1934 interest in and investigation of air-borne infection lagged. Then Wells (1934) challenged the generally accepted principles and conducted some relatively simple experiments in which he rediscovered and extended the largely ignored findings of earlier workers. He sprayed a variety of bacteria and viruses into a closed chamber and demonstrated that they remained suspended in a viable and infectious form for hours and even days. He proposed the term "droplet nucleus" for the tiny bacteria-laden particle that results from drying of the droplets which emanate from the mouth. He showed that these droplet nuclei, which may remain suspended in air for hours, are highly susceptible to the lethal effect of ultraviolet irradiation. He initiated field trials with ultraviolet lights in the attempt to control epidemics of communicable diseases in schools and cross infections in hospital wards.

Following Wells' original contribution, interest in air-borne infections revived. It was recognized that cross infections on communicable disease and pediatric wards remained at least a minor and occasionally were a major problem in spite of presumably adequate isolation precautions. A certain low but still serious residue of

surgical wound infections occurred without known breaks in aseptic techniques. The question was raised whether or not air-borne infection was an important factor in the occurrence of epidemics of contagious disease in centralized schools and of acute respiratory disease and beta hemolytic streptococcal infections among military recruits. Following Wells' example, ultraviolet irradiation was applied widely in attempting to control these problems (Subcommittee for the Evaluation of Methods to Control Air-Borne Infection, 1947; Subcommittee on Air Sanitation, 1950).

From Moulton, F. R., *Aerobiology*.

**Fig. 2-1. A violent sneeze completed.**

Over 40,000 particles are here shown. The eyes are characteristically closed. A few droplets may be seen coming from the nostrils.

The development of serological methods for typing beta hemolytic streptococci provided a new tool for studying air-borne infection. Applied first in England and later in this country, it was found that the air, the dust, the blankets, and in fact the total environment of hospital wards and military barracks may become grossly contaminated with one or more strains of specific streptococci. Certain types of patients, particularly those with purulent discharges such as otitis media, sinusitis, septic skin infections, or merely carriers with a strongly positive nasal culture have a peculiar capacity to disperse large numbers of streptococci. These findings led to the development of dust suppressive measures on the assumption that the gross contamination of the dust in such environments became a primary reservoir for subsequent human infections. These were applied in large scale field trials in military populations during and subsequent to World War II.

An intensive search for other methods of disinfecting air was made. A wide variety of chemical substances in the form of aerosols and vapors were tested and found to have bactericidal effects of varying degrees and markedly varying toxicity and corrosiveness. Of these substances, the relatively nontoxic glycols, particularly

tri-ethylene glycol, received greatest attention in the laboratory and in limited field tests.

Throughout the period from 1934 to 1945 the revival of interest in air-borne infection led some of the more enthusiastic workers to predict that the application of engineering methods of air sanitation would eventually lead to the same successful control of the respiratory and contagious diseases as had followed the application of engineering technics to the control of the enteric diseases. In many circles it became the fashion to refer to the respiratory and contagious diseases as "the air-borne infections."

FOURTH PERIOD. Despite these extensive studies pointing toward the possible importance of air-borne infection, the results of practical field trials with the newly developed engineering devices for aerial disinfection were generally disappointing, except in a few limited types of environments.

Ultraviolet lights were installed in operating rooms, and in pediatric and contagious disease wards. Further reductions in the already low incidence rates of cross infections were reported in several well-controlled studies. In other studies, slight, if any, benefit was achieved. The guarded conclusion was justified that this procedure has limited application in such environments, when the lights are properly installed and maintained. It is clear, however, that they are not a substitute for strict isolation precautions.

Ultraviolet lights had extensive tests in primary and secondary schools for control of the acute contagious diseases. The report of Wells' early experiment in the Germantown school was impressive. An epidemic of measles spread more extensively through the unirradiated upper grade class rooms than through the irradiated lower grades, in spite of the much larger number of susceptibles among the younger children. Repetition of this dramatic result, however, has not been reported, either by Wells or others. In subsequent studies, only slight effects from the irradiation could be discerned, such as the prolongation of the epidemic, changes in epidemic patterns, and slight differences in attack rates among susceptibles. While these effects suggest that the ultraviolet light may partially reduce classroom spread of infection, they are of only theoretical interest. The extensive experience of numerous studies is sufficient to warrant a confident conclusion that the presently available methods of ultraviolet irradiation in schools are not practical for controlling contagious disease epidemics. Furthermore, even if they were effective, there are valid reasons against their use. The only effect that could be expected would be to postpone acquisition of infection to older ages or adulthood when the consequences of certain of these diseases are more serious.

The use of ultraviolet lights in naval barracks resulted in reductions of approximately 20 per cent in the incidence of acute respiratory diseases. While the results are quite variable, there was sufficient consistency in the findings over a period of six consecutive years to indicate that air-borne infection played at least a partial role in the problem. The methods used, however, failed to prevent the introduction and epidemic spread of common respiratory diseases, primary atypical pneumonia, influenza and beta hemolytic streptococcal infections in the irradiated barracks.

These trials did not provide a definitive test of the importance of air-borne infection in such environments. Only a 50 to 75 per cent reduction in bacterial contamination of the air was achieved. The failure to effect a greater reduction in

disease may have resulted from inadequate sterilization of the air or from the possibility that contact and droplet infection is the dominant mode of spread. Only when a much greater disinfection of the air is attainable will this question be answered.

The oil treatment of floors and bedding in military barracks was tested extensively with slight if any beneficial effects. Although this simple and readily applied procedure achieved a substantial reduction in bacterial contamination of air, particularly during bed making and floor sweeping, only inconclusive or no reductions in the incidence of epidemic acute respiratory disease and hemolytic streptococcal infections were reported. These studies clearly indicated that dust suppressive measures alone were insufficient for controlling epidemics of respiratory disease among recruits.

Technical problems in the dissemination and maintenance of bactericidal concentrations of glycol vapors in large occupied spaces precluded adequately controlled field trials. Limited tests in hospital wards and single barracks buildings indicated that a substantial reduction in aerial bacteria could be achieved, particularly if dust suppressive measures were carried out concomitantly. The epidemiological observations have been insufficient to warrant valid conclusions (Krugman and Ward, 1951).

Several attempts were made to use glycol vapors in ventilating ducts and air conditioning systems in large offices or industrial establishments to control the common cold. Serious technical limitations were encountered. In those studies where epidemiologically controlled observations were attempted, no benefit resulted. Such negative findings might well be anticipated since workers have multiple daily opportunities to acquire infections outside of working hours.

Thus, the hopes and predictions that the engineering methods of air sanitation would find wide general application failed to materialize. The impressive bactericidal effects of ultraviolet light and glycol vapors under laboratory conditions were less impressive in the field. They could be installed only in certain types of environments. Infections occurring in test populations outside the treated spaces could not be prevented and were difficult to evaluate. It became apparent that these methods had only limited application to highly specialized and regimented populations, such as contagious disease and pediatric wards and certain types of operating rooms where contact infections could be rigidly controlled and where residual air-borne infections remained important. Even in these environments the methods of air sanitation have had only limited acceptance, presumably because of the cost of their installation and maintenance and because during the period of their development the serious consequences of cross infections have become minimized due to the therapeutic and prophylactic use of antimicrobial drugs and gamma globulin.

While substantial evidence was accumulated that air-borne infection did occur at certain times and places, the question of its relative importance compared with contact and droplet infection remained unanswered; it can be expected to vary with different specific diseases. The definitive experiment to test its importance in large population groups for any one infection has yet to be performed. Certainly the present evidence accumulated is insufficient to justify discarding Chapin's views or to support the enthusiastic claims of the commercial exploiters of ultraviolet lights and glycol vaporizers. The term "contagious," meaning contact, remains a more appropriate adjective than "air-borne" to describe the common respiratory infections.

**FIFTH PERIOD.** While the hopes for broad practical application of the methods of aerial disinfection in the control of respiratory diseases failed to materialize, limited applications were discovered. Improvements in existing methods and new technics can be anticipated. Therefore, the basic principles of the present methods should not be ignored. Furthermore, the increasing recognition of the critical importance of particle size in the penetration and retention of particulates in the respiratory tract has opened new areas of interest in air-borne infection. Among these are pulmonary tuberculosis, certain pulmonary mycoses and accidental laboratory infections. The principles involved in these new areas have important application in any consideration of the potentialities of biological warfare.

## METHODS OF CONTROLLING AIR-BORNE MICRO-ORGANISMS

Bacterial contamination of the air may be controlled by four general methods: (1) mechanical ventilation; (2) ultraviolet irradiation; (3) disinfectant vapors; and (4) dust suppression.

**Ventilation.** The simplest of all measures for removing contaminants from enclosed spaces is natural ventilation from open windows. This is a generally accepted practice as part of terminal disinfection and is still advocated as a routine measure in contagious disease wards, particularly in Great Britain. The limitations of such a procedure are so obvious that it cannot be considered an effective measure to control air-borne infections.

Similarly, the use of forced ventilation and air conditioning is inadequate. In occupied spaces the production of new air-borne bacteria resulting from normal human activity is so great that the rate of air change necessary to reduce the contamination substantially is uneconomical and causes unpleasant draftiness. Furthermore, the almost universal practice of recirculation of air in ventilating systems may serve to disseminate air-borne pathogens (Yaglou and Wilson, 1942).

Under specialized conditions the use of controlled air currents, either alone or in conjunction with physical barriers, filters, precipitators, or other mechanical means of removing particulates from the air may have limited applications. In operating rooms, surgical dressing rooms, nurseries for premature or newborn infants and other specialized environments where the consequences of infections may be serious, the investment in expensive and carefully designed air conditioning systems may well be justified.

In research laboratories dealing with highly infectious agents, the risk of air-borne infections to personnel and among experimental animal colonies is now clearly demonstrated. Here controlled ventilation, often augmented by other means of aerial disinfection, is essential.

**Ultraviolet Irradiation.** The disinfectant action of ultraviolet light has long been known and has been accurately quantitated. Wave lengths in the range of 2,500 Ångstrom units are most bactericidal. The development of the low pressure mercury vapor lamp which emits its maximum radiation in the wave length 2,537 Å.U. has made possible practical and reasonably economical devices. Under laboratory conditions, using finely atomized suspensions of bacteria or viruses, practical intensities of irradiation induce a rate of removal equivalent to 100 or more air changes per hour. Under field conditions similar rates of reduction are not achieved because the

bacterial contaminants are of varying size, from small droplet nuclei to large dust particles. Naturally-occurring bacteria in the air may have a coating impermeable to the bactericidal rays. Nevertheless, substantial reductions in bacterial air counts of 50 to 75 per cent have been repeatedly achieved under the rigorous conditions of crowded naval barracks (Moulton, 1942).

Certain practical limitations have been encountered in the utilization of ultraviolet irradiation for the control of air-borne infection in occupied spaces. Germicidal intensities are injurious to the human skin and conjunctivae, thus requiring that the radiation be confined to the upper air of rooms above the head level. Skilled engineering services are necessary for the supervision of each installation to insure maximum intensities in the upper air and at the same time to avoid reflections from ceilings, walls or other surfaces that may "burn" the occupants. The use of ultraviolet absorbent paints may be necessary. Numerous types of carefully designed fixtures and practical photometers to measure intensities are commercially available. Continuing supervision of each installation is necessary for regular cleaning of the lamps and their reflectors and for the testing and replacement of tubes showing diminished output.

In pediatric wards and operating rooms, carefully placed light screens or "curtains" may be installed at the entrance to rooms, or cubicles or around the operating site. Such procedures can be used safely only when patients are rigidly controlled and when all medical and nursing personnel are strictly indoctrinated and disciplined as to the dangers of direct exposure. That these problems are not insuperable is demonstrated by the fact that numerous installations have been in service for long periods.

More serious limitations to the generalized use of ultraviolet irradiation in occupied spaces are theoretical in nature. Since the intense rays must be confined to the upper air, only those droplet nuclei which circulate through the upper air can be disinfected. In occupied spaces this circulating air is continuous and quite rapid, but at best only a partial reduction in bacterial contamination can be expected. Successful use of ultraviolet irradiation, therefore, depends on the as yet unproved premise that infectious disease fails to spread in an inclosed space when the concentration of the air-borne pathogens is lowered below a certain threshold. Furthermore, since the rays are less effective against larger particles, little, if any, effect can be expected against dust-borne infections (Subcommittee for the Evaluation of Methods to Control Air-Borne Infections, 1947; Subcommittee on Air Sanitation, 1950).

**Disinfectant Vapors.** Many chemicals have been shown to have marked bactericidal action when dispersed in air. These include the halogens, hypochlorites, lactic and other hydroxy acids, hexylresorcinol, and the glycols (Bourdillon and others, 1948). Of these, the glycols, particularly tri-ethylene glycol, appear to be the most practical because of their high bactericidal potency, reasonable cost, and freedom from odors, toxicity and corrosiveness.

Originally, the mechanism of action of these substances was assumed to be collisions between bactericidal particles and aerosol droplets of the disinfectant. Subsequent laboratory experiments and theoretical considerations indicate that condensation of vapor onto the bacteria-laden particles is a more satisfactory explanation, at least for the glycols.

In vitro studies show that the glycols are only moderately bactericidal in solution. Concentrations of 50 per cent or greater are needed to produce a rapid killing rate. Extremely minute concentrations of the same substance in the air, however, produce a most dramatic bactericidal effect.

The explanation for this apparent difference lies in the low vapor pressures of the glycols. To be effective, the saturation in the air must exceed 50 per cent. Since air-borne bacterial particles are necessarily small and contain at least some water, and since the glycols are highly hygroscopic substances, an equilibrium between the concentration of glycol within the particle and in the surrounding air is rapidly reached. Depending on the relative humidity, this equilibrium concentration may equal or exceed that which is rapidly bactericidal in solution. If the humidity is too high the equilibrium concentration is too low. In very dry atmospheres, bacterial particles contain so little water that insufficient glycol condenses. At intermediate humidities, roughly 20 to 50 per cent, effective concentrations are rapidly attained. It is a fortunate circumstance that the relative humidity of many types of occupied space in winter months usually falls within this range.

Glycol vapors have one distinct advantage over ultraviolet irradiation because they may permeate the entire atmosphere of an enclosed space. Thus, pathogens emanating from an infected individual as small droplets from the mouth or nose begin to absorb the vapor molecules immediately and, in the process of drying, bactericidal concentrations are built up within the droplet with great rapidity. Therefore, glycol vapors can be expected, at least on theoretical grounds, to induce a greater reduction than ultraviolet irradiation in the concentration of fresh infectious nuclei (Subcommittee for Evaluation of Methods to Control Air-Borne Infections, 1947; Subcommittee on Air Sanitation, 1950).

Serious limitations in the practical use of glycol vapors still remain to be overcome. As with ultraviolet light, the vapors have little effect on larger or dust particles, presumably because they are coated with substances that neutralize the effect or because dried bacteria are resistant.

Another difficulty that has yet to be solved on an economical basis is maintenance of adequate saturations of vapor in occupied spaces. The glycol output of many commercially available vaporizers is grossly inadequate. The hourly and daily variations in the indoor temperature and relative humidity resulting from occupancy and outdoor conditions require a method of vaporization that will respond promptly to a variable demand. One simple procedure for insuring continuous bactericidal concentrations is the maintenance of a slight fog in the room at all times, which means that the saturation of the vapor is being approached or exceeded (Subcommittee on Air Sanitation, 1950).

**Dust Suppression.** The control of the dust and lint in the air that arises from the floors, blankets, bedding and clothes during normal activity is based on the principle of making these particles sticky. Light paraffin or spindle oils are quite satisfactory. Unvarnished soft wood floors, such as exist in many types of military barracks and schools, may be treated with a saturation dose of oil, thereby effectively laying the dust for several months. Hardwood floors require less oil but more frequent treatments. Painted concrete, waxed or linoleum floors should not be oil-treated but these are usually less dusty and the daily use of oiled sweeping compounds is helpful.

The oiling of floors darkens the surfaces, increases slightly their slipperiness, and

may soil the feet, shoes, trouser cuffs, and clothes of occupants. But these minor disadvantages are more than overcome by the greater ease of routine housekeeping and marked reduction in dustiness.

Wholly practical methods are available for the oil impregnation of blankets, bedding and certain types of clothing (Puck and others, 1946; Loosli and others, 1946). By adding a stable emulsion of a purified paraffin oil, made with a neutral detergent, Triton NE, to the final rinse in the laundering process any desired deposition of oil on the fabric can be attained. A concentration of approximately 2 per cent by weight makes no appreciable change in the appearance or feel of the material, yet gives it remarkable dust and bacteria-holding properties. Woolen fabrics retain these properties for many months, even after subsequent washings. Cotton fabrics require re-treatment.

In military barracks or hospital wards where floors and bedding have been oil-treated, substantial reductions of 90 per cent or greater in the bacterial contamination of air have been consistently achieved. The greatest effect is noticed during sweeping and bed making, when in untreated wards gross contamination regularly occurs.

Although repeated studies of dust suppressive measures in the control of respiratory diseases have largely failed to demonstrate consistent benefits, oiling procedures have recognized advantages from the point of view of "good housekeeping." Furthermore, since neither ultraviolet light nor glycol vapors have an appreciable effect on dust-borne bacteria, dust suppression should be utilized whenever these other methods of aerial disinfection are employed.

## RETENTION OF PARTICLES IN THE RESPIRATORY TRACT

The relation between the size of inhaled particles and the depth of their penetration and retention in the respiratory tract has explained many confusing problems in the epidemiology and pathogenesis, not only of industrial hazards such as silicosis, but also of air-borne infections (Hatch, 1942; Brown and others, 1950). Furthermore, effective inhalation therapy with antimicrobial and other drugs depends on this principle.

Theoretical calculations applying established physical principles to the known dimensions of the respiratory tract and experimental studies using a variety of different techniques, including radioactive isotopes, have led to essentially similar results (Wilson and LaMer, 1948). They show that the respiratory tract is an exceptionally good filter, considering the volume of air which passes through it.

Particles larger than five microns in diameter are almost completely removed in the nose and upper respiratory passages. Below five microns in size progressively increasing proportions of inhaled particles reach the terminal bronchioles and alveoli. In the range of one micron from 50 to 60 per cent penetrate to the alveoli and are trapped there. Below this range, alveolar deposition again decreases because more particles are exhaled. In the submicroscopic range below .25 micron an increase in retention is theoretically expected because Brownian movement comes into greater action.

The fate of inhaled particles larger than five microns is quite different from that of the smaller particles. Those that impinge on mucus overlying ciliated epithelium

are wafted to the oropharynx where they are most likely to be swallowed or occasionally expectorated. Those that impinge in the anterior chamber of the nose will be wafted to the external nares. The smaller particles that are retained beyond the ciliated epithelium in the terminal bronchioles and alveoli must be removed by tissue mechanisms, principally phagocytosis. Thus, for toxic substances, such as silica, minerals, or metallic poisons, and for those pathogenic agents not normally infective through an upper respiratory portal of entry, inhalation of large particles is essentially equivalent to a slow gastro-intestinal instillation. Inhalation of particles progressively smaller than five microns becomes increasingly similar to an intratissue or subcutaneous inoculation. (See material on dust, page 1044.)

Inhalational therapy with sulfonamide drugs and penicillin utilizes these same principles. In the treatment of nasopharyngeal or sinus infections large particles 20 microns or more in diameter are indicated (Committee on Public Relations, 1950). For broncho-pulmonary infections where local deposition on the bronchioles as well as absorption into the blood stream are required, then particles of two to six microns should be used. If systemic absorption is the primary objective, particles from 0.6 to 1.6 microns are recommended.

These principles have direct application to the mode of spread of respiratory infections. For those infectious agents, such as the streptococcus and the diphtheria bacillus, which have the capacity to invade the tissues of the nose and pharynx, and for agents such as influenza virus and *H. pertussis* which invade the respiratory epithelium of the nasopharynx, the trachea and larger bronchi, no special problem arises. Air-borne particles, large and small, can reach these sites by inhalation. In contrast, those infectious agents that do not normally invade these sites, but rather infect only through the terminal bronchioles or alveoli, must be dispersed in the air in exceedingly fine particles. It is easy to visualize how infections of the upper respiratory tract can be spread as readily by direct or indirect contact as by inhalation. It is difficult to visualize how an infection, with its primary portal of entry the alveolus, can originate except by air-borne infection.

The upper limit to the size of particles that can reach the alveoli is strikingly similar to the dimensions of single bacterial cells, fungal spores, rickettsiae and the virus elementary bodies. This should not be considered as mere coincidence but rather as a fact of special biological significance. The mammalian lung is an intricate structure that has developed by the evolutionary process of natural selection. Its dimensions have been determined on the one hand by the viscosity of air and the physiological needs of respiration, and on the other hand by the obvious necessity to filter out most noxious particulate matter. The fact that the human lung successfully removes particles larger than single bacterial cells should be regarded as one of many factors contributing to the survival of the species.

Furthermore, pathogenic agents rarely exist in nature as single cells; rather they tend to grow in clumps or chains. They are almost always intimately mixed with mucus, pus, saliva, feces or other moist organic matter. This means that when they are extruded into the open environment they tend rapidly to adhere to surfaces or to inert particles of dirt, dust or lint and thereby become even larger.

Certain exceptions to this general argument should be noted. During a sneeze, myriads of small droplets are produced. The violence of this atomization may produce a fracturing of bacterial clumps leading to a dispersal of a few single cells. If

viruses are present in the sputum or saliva, some of these may well be dispersed in small particles.

Under certain conditions the environment may become grossly contaminated with pathogenic agents. For example, some nasal carriers of hemolytic streptococci and patients with streptococcal skin infections or draining wounds may disseminate prodigious numbers of bacteria. The placental tissues and postpartum discharges of sheep and cattle infected with Q fever and brucellosis contain high concentrations of the infectious agents which contaminate the local environment. The careless tuberculous patient with strongly positive sputum must disseminate large numbers of organisms into his immediate surroundings. Under such specialized conditions of gross contamination, sweeping, bed making, and other normal activity may well raise into the air an occasional small infectious particle along with a large number of big particles.

The pulmonary mycoses constitute another special situation. Here the pathogenic agents presumably exist and grow in nature. Coccidioidomycosis occurs in dry climates, histoplasmosis in areas of higher relative humidity. Both are almost certainly air-borne infections with the portal of entry in the alveolus of the lung. Single infectious spores may well be released into the air by natural processes not yet well defined.

Pulmonary tuberculosis constitutes another special problem. The locus of the primary lesion in the lung parenchyma strongly suggests the terminal bronchioles or alveolus as the portal of entry. Since the dimensions of the tubercle bacillus are approximately two by six microns, only a single cell or a very small clump of bacilli can reach this site by inhalation. A large majority of primary lesions are known to be single, which suggests that the primary complex arises from a single small particle. Wells and others (1948) have reported that in rabbits the inhalation of large particles results in none or very few pulmonary lesions, whereas the inhalation of equal numbers of small particles results in many pulmonary tubercles. Lurie and others (1950) have amply confirmed and expanded this observation. In a long series of tests they showed that the inhalation of single viable particles produced discrete tubercles in numbers equal to the estimated particles retained in the alveoli.

The concept that primary pulmonary tuberculosis is predominantly an air-borne infection most adequately accounts for some aspects of the epidemiology of the disease. The frequency of single primary lesions fits with the probable infrequency of very small infectious particles in the air. This in turn is consonant with the known relatively noninfectious character of tuberculosis. Some intimate household contacts may be exposed to open cases for several months without becoming tuberculin positive. Increasingly large proportions of the adult population are remaining uninfected in spite of the known numbers of sputum-positive cases at large. The initial pulmonary lesion apparently results from the occasional small particle that occurs during a gross environmental contamination or from some other as yet poorly defined mechanism that introduces single cells into the air. Thus, the concept that primary pulmonary tuberculosis may be predominantly an air-borne infection rather than a contact infection deserves serious consideration.

While these exceptions are of great importance in the epidemiology of certain specific infections, they do not negate the general conclusion that single pathogenic cells are only rarely dispersed into the air under natural circumstances. Rather, it

would seem that the human species has not been forced to contend with a wide variety of finely dispersed bacterial aerosols and, therefore, has not faced the biological necessity of developing a natural mechanism to defend against them.

Artificial circumstances present an entirely different picture. Using modern laboratory technics, many pathogenic agents may be grown in almost limitless quantities and may be dispersed into the air as single cells. When this occurs accidentally, as in laboratories, serious infections have often ensued (Sulkin and Pike, 1949; 1950).

Until recently the commonly accepted mode of transmission of these accidental infections was contact resulting from errors in technic. Much evidence supported this view. Many infections had been observed to follow relentlessly upon such incidents as the aspiration into the mouth of a virulent culture during pipetting, or the nicking of the hand during autopsy, or the jabbing of the finger during animal inoculation, or the gross contamination of the whole environment when a flask of agent was spilled or broken in a centrifuge.

From Johansson, K. R., and Ferris, D. H., *J. Infect. Dis.*, 78:241, 1946, plate II.

**Fig. 2-2. Blowing last drop from pipette.**

Numerous laboratory infections have occurred, however, in the absence of known breaks in technic, even when extreme precautions were being consistently followed.

Of special interest are the occasional explosive epidemics that have occurred in research laboratories. These have involved large numbers of persons in widely separated rooms, and have occurred under circumstances that apparently preclude direct contact (McCoy, 1930, 1934; Newitt and others, 1939; Huddleson and Munger, 1940; Huebner, 1947).

Recognition of the air-borne origin of many of these obscure infections and

unexplained epidemics developed slowly but is now generally accepted. Important in this change has been the association of accidents with certain laboratory procedures, such as intranasal instillations, centrifugation of concentrated suspensions of infectious agent, and grinding of tissues in the Waring Blendor. These procedures often produce invisible clouds of finely dispersed infectious aerosols.

Of special interest are the studies of Johansson and Ferris (1946) which showed that aerosols were produced even by routine procedures, as removing a cotton plug from a flask, transferring cultures, withdrawing a hypodermic needle from a stoppered vial, or blowing the last drop from a pipette. These studies illustrate in a graphic fashion the manifold opportunities for aerial contamination that exists in laboratories, and point to the necessity for redesigning of laboratory buildings and equipment to protect personnel working with infectious agents. In such planning, specially designed hoods with controlled air currents, ultraviolet irradiation, and disinfectant vapors all have important implications.

Thus, the recognition of the relation of size of inhaled particles to the locus of their retention in the respiratory tract has led to better understanding of air-borne disease and the mechanisms for protection. At the same time, it has led to the contemplation of its possible use for destructive purposes in warfare. The occurrence of infections among laboratory workers demonstrates the possibility that an enemy might be able to create purposeful epidemics by reproducing similar conditions. Whether such an artificially induced epidemic would be subsequently propagated by natural transmission in the population attacked is open to question. Nevertheless, the potential menace of the creation of clouds of infective particles liberated in an enclosed space by saboteurs or diffused in air currents over wide areas against large populations in open warfare by munitions cannot be ignored.

## CONTAGIOUS DISEASES SPREAD LARGELY THROUGH FECAL DISCHARGES

Grouped together in this chapter are diseases and infestations transmissible from man to man, caused by parasites which enter the mouths of human beings with food and drink, can develop and multiply in some portion of the alimentary canal, are capable of disturbing physiological functions, and whose progeny are discharged in the feces. Their continued propagation is dependent principally upon fecal dissemination. Per contra their control is dependent upon measures included under the general designations of personal hygiene and sanitation, intended to reduce the opportunities for contamination of food and drink with fecal material. Although they have this much in common, they present a wide range of differences. The causative agents are certain species of intestinal bacteria, protozoa and helminths. Each has its own peculiar host relationships, biological requirements, potential pathogenicity, and ability to survive in the external environment. Each, therefore, has its own characteristic clinical, pathological and epidemiological pattern. From the point of view of prevention, each presents a distinct and separate problem.

### CHOLERA

Cholera is an acute specific infection of the alimentary tract due to the cholera vibrio. The onset may be with a moderate diarrhea which increases in severity, but it is much more frequently sudden with violent purging and vomiting. There are very copious, watery evacuations, the stool taking on a typical "rice water" appearance, nonoffensive whitish fluid with flakes of mucus and occasionally streaks of blood. The diarrhea is followed shortly by diffuse watery vomiting. In the more severe cases, symptoms attributable to fluid loss and toxic absorption develop, notably muscular cramps, suppression of urine and collapse. Unless the rapid dehydration is checked by the parenteral administration of fluid, the course is rapidly fatal. The patient either recovers or dies within a few days. The case fatality rate has varied from 20 to 85 per cent in different outbreaks, depending upon the completeness of reporting of cases and the availability of good medical care. In the presence of an epidemic the clinical recognition of cholera presents no difficulties. Sporadic, mild cases are more difficult to recognize. The diagnosis is made by isolating the cholera vibrio from the stool, sometimes also from the vomitus of patients. The incubation period is short, frequently from one to two days, rarely over five.

**Prevalence.** According to Hirsh: "In the nineteenth century annals of pestilence, the year 1817 stands as one charged with fatality to the human race. It was in that year there began the epidemic extension over India of a disease which had previ-

ously been known only as endemic in a few districts of the country; in that and the following year it overran the whole peninsula, in a short time it crossed the borders of its native territory in all directions, penetrated in its further progress to almost every part of the habitable globe, thus acquired the character of a world-wide pestilence, which has repeatedly since then entered on its devastating campaign and has claimed its many millions of victims."

In the nineteenth century cholera repeatedly spread along the routes of trade and travel to Europe, Asia, Africa, and America. There have been five periods of pandemic spread, during four of which it has reached the North American continent; one from 1817 to 1823, another 1826 to 1837, a third 1846 to 1862, a fourth from 1864 to 1875, and a fifth from 1883 to 1896. In 1832, it entered the United States by way of New York and Quebec and reached as far west as the military posts of the upper Mississippi. The disease occurred in 1835 and 1836. In 1848, it entered the country through New Orleans and spread widely up the Mississippi and was dragged across the continent by the searchers for gold all the way to California (1849). It again prevailed widely through this country in 1854, having been introduced by immigrant ships into New York. In 1866 and 1867 there were less extensive epidemics. In 1873, it was again introduced into the United States through the agency of the mercantile marine. It prevailed especially in the Mississippi Valley, causing a "deplorable mortality." As a result of Congressional action this epidemic was thoroughly investigated by John M. Woodworth, Supervising Surgeon, U. S. Marine Hospital Service, in 1875. His report was the basis of the maritime quarantine regulations which were subsequently promulgated in this country to prevent importation of the disease. Since then, only occasional cases at seaports have been reported.

In 1892, the great epidemic of Hamburg occurred, and cases were brought by transatlantic liner to New York but the disease failed to spread. Since the turn of the century, in spite of disordered conditions of World War I and World War II, cholera has been unable to establish a foothold in the countries of northern Europe, the British Isles, North and South America. It has been limited to southeast Asia with occasional spread along lines of travel into Asia Minor, southeastern Europe, Russia, China, the Philippines, Japan and adjacent territories (Swaroop and Politzer, 1952).

In southeast Asia the disease is continuously endemic, in certain parts of India, particularly in Bengal, the Ganges Delta region, and in central and southeast Madras. There are also areas in which it is currently endemic: in Burma, Indo-China, Thailand and the Yangtze Valley of China. At irregular intervals it propagates from these centers into the adjacent areas. That it still remains a threat to neighboring countries is illustrated by the fact that Egypt was free from cholera from 1902 to 1947. In the latter year it was introduced, prevailed widely in the lower Nile Valley, and before it again disappeared in 1948 had caused some 20,462 deaths in 3 months.

**The Cause.** Although the idea that a living micro-organism was the cause of cholera had long been suspected, it was not until 1883 that Koch discovered vibrios in the stools of cholera patients in Egypt. Later, at the Medical College of Calcutta, India, he reported finding the same kind of vibrios in the stools of every case of cholera he examined. Although elements of proof were lacking, Koch's theory received general credence and the matter was left where it stood for some years.

Confusion was caused by the fact that there are a large number of vibrio forms found in nature from which the cholera vibrio had to be differentiated.

Advance in this direction was afforded by the demonstration of the Plesker phenomenon in 1893 and later the use of the agglutination test. Although agglutination narrowed down the number of suspected vibrios, it did not sharply distinguish those which were pathogenic from those which were non-pathogenic. It took a good many years of study and research before reasonably satisfactory methods were developed for this purpose. A classification based principally upon antigenic analysis by agglutination was proposed by Gardner and Venkatraman in 1935. Their work has recently been confirmed by Burrows and others (1946). Study of the thermostable somatic antigens of a large number of strains showed that the vibrios could be divided into six immunological groups which they designated O subgroups I to VI, inclusive. All of the true cholera vibrio strains fell into group I. Four immunologic subtypes are recognized, viz., Ogawa, Inaba, Hikojima and Burrows. The potential pathogenicity of a fifth type, the El Tor vibrio, is in doubt.

Using monospecific antisera made from these subtypes, it is now possible to identify pathogenic vibrios with confidence. This is particularly true when the strains examined come from human sources. The limits within which mutations may occur in nature, producing pathogenic from non-pathogenic forms, and vice versa, is still a matter of uncertainty.

Cholera infection does not occur naturally in any animal species other than man, although a somewhat similar condition may be readily produced in very young guinea pigs and rabbits. Small laboratory animals are susceptible to the action of the endotoxin of the vibrios and to products of their metabolism when cultured material is injected intraperitoneally or given by mouth in large quantities.

Accidental infections of laboratory workers have occurred and have been fatal, but they are comparatively rare. The organism may lose its pathogenicity on repeated transfer in artificial culture.

**Diagnosis.** In the infected individual the vibrios are confined almost entirely to the gastro-intestinal tract. They are usually found in large numbers throughout its whole length. They escape from the body in stools and vomitus. The patient does not usually pass cholera vibrios in stools for more than five days from the time of first infection. Diagnosis is made by isolating the vibrios from the patient's stool or a rectal swab, occasionally also from the vomitus.

A clinical diagnosis of cholera may be presumptively supported by finding large numbers of comma-shaped bacilli on direct microscopic examination of stained preparations, or in hanging drops, of the mucus flakes from the stools. Because of the delicacy of the organism, cultivation procedures should be carried out as promptly as possible. Usually, the suspected fecal material is streaked on alkaline (pH 9 to 9.6) agar and inoculated heavily into a tube of peptone water of the same pH. Portions of suspected colonies on an agar plate are rubbed upon a slide in small pools of specific serum of proper dilution, or a pure culture suspension is added to serial dilutions of (Inaba and Ogawa) diagnostic sera incubated at 37° C for one hour and examined for agglutination (Diagnostic Procedures and Reagents, 1950).

**Survival.** Of great importance in the epidemiology of the disease is the ability of the causative organism to survive outside the human body. It has no resistant

phase. *Vibrio cholerae* dies in a few hours in the fecal specimens at room temperature. In fecally contaminated clothing it survives for one to three days in a moderately moist temperature but is easily killed by drying. Under favorable conditions of storage in a cool moist environment, vibrios may remain viable for from four to seven days on the surface of fresh fruits and vegetables. In concentrated sewage it dies in 24 hours. On the other hand, in pure water it also dies rapidly. Survival of cholera vibrios in water can be promoted experimentally. For example, vibrios will survive for some weeks in water with a concentration of 0.02 per cent salt and 1/5,000,000 peptone with pH range between 6 and 9. Analogous conditions are approached in some of the natural waters in Bengal.

**Carriers.** Studies on the mode of spread of cholera in Hamburg in 1892-1893 led Robert Koch in 1893 to an appreciation of the role of the carrier "Vibrionenträger" in disease transmission. He observed that among a number of persons who have been exposed to cholera infection the resultant cases may show the whole scale from the severest of rapidly fatal cases down to the mildest imaginable, demonstrable only by bacteriological examination. He also observed that infectious matter might be contained in the evacuations of patients immediately before and just after the acute illness, i.e., at a time when association with others was not yet or no longer regarded as dangerous. This explained why human association could propagate cholera through the medium of apparently healthy persons.

A subclinical or contact carrier, like the case of cholera, does not usually pass true cholera vibrios in stools for more than five days. In the Egyptian experience of Kamal, in 1948, in which members of the household in which a case had occurred were released from isolation after two negative stool examinations three days apart, it was found that most of the carriers had become free by the tenth day; a small percentage continued to be positive for vibrios up to the fifteenth day. The longest carrier state observed was 26 days. There is no record up to the present of an individual harboring the organism continuously for more than one month.

**Modes of Transmission.** Cholera is spread by man from place to place. It follows the lines of trade and travel. Seaports are invariably first attacked. The epidemic at Hamburg in 1892 was brought to that port by immigrants on board vessels from Russia. There are many similar instances. In 1849 many a gold hunter found another Eldorado than the one he was searching for, as cholera was dragged across the continent by the caravans seeking fortunes in California. The same thing takes place in the Indian pilgrimages to Mecca.

The cholera vibrio enters the digestive tract through the mouth. It is taken in food and drink. Infected water is a frequent medium of transference, and probably the chief vehicle of the great epidemic outbursts. Cholera, however, may be transferred from man to man directly, also indirectly by flies, fingers, food, and all the innumerable channels from the anus of one man to the mouth of another.

**Water-Borne Outbreaks.** The cholera vibrio may live and even multiply in water. Koch in his original investigations found vibrios in the foul water of a tank in India which was used by the natives for drinking purposes. It has been shown by experiment that the cholera vibrio may multiply to some extent in sterilized river water or well water; and that it preserves its vitality in such water for several weeks. In recent times vibrios have been found not infrequently in the water of wells, water mains, rivers, harbors, canals, and even sea water (the North Sea near the mouth

of the Elbe), which have become contaminated with the discharges of cholera patients. It is plain from the nature of the case that polluted water must play a very large rôle in spreading this infection.

Cholera in London in 1854; the Case of the Broad Street Pump. Cholera was prevalent in London in 1854, but prevailed with epidemic intensity in the district about Broad Street. The circumstances were studied by John Snow. His monograph on the "Mode of Communication of Cholera," which has been reprinted by the Commonwealth Fund (1936), with an introduction by Wade Hampton Frost, is a classic which every student of epidemiology should read. This focus was conspicuously circumscribed in area, and the disease was virulent, with great fatality. It was one of the earliest instances, if not the first, in which water was proved to convey a specific disease. No less than 700 deaths occurred in St. James Parish during the seventeen weeks that the cholera raged. The death rate was 220 per 10,000 in the parish, which contained a population in 1851 of 36,406. In the districts adjoining St. James Parish the death rate varied from 9 to 33 per 10,000.

Snow made a careful epidemiological study of the outbreak and compiled the data shown in Table 3-1.

It will be seen that the disease broke out with special intensity upon August 30 and declined noticeably after September 10. The pump had been removed on September 8. Snow's inquiry showed that most of the victims had preferred or had access to the water of the Broad Street well, and in a few cases only was it impossible to trace any connection with that source. Thus, with regard to 73 deaths

occurring in the locality of the pump and studied especially with reference to this point, it was found that there were 61 instances in which the deceased persons used to drink the water from the pump in Broad Street, either constantly or occasionally. In six instances no information could be obtained, and in six cases it was stated that the deceased persons did not drink the pump water before their illness.

On the other hand, Snow discovered that, while a workhouse (almshouse) in Poland Street was three-fourths surrounded by houses in which cholera deaths occurred, out of 535 inmates of the workhouse only five cholera deaths occurred. The workhouse, however, had a well of its own in addition to the city supply, and never sent for water to the Broad Street pump. If the cholera mortality in the workhouse had been equal to that in its immediate vicinity it should have had 50 deaths.

After the original map by Dr. John Snow.

Fig. 3-1. Asiatic cholera and the Broad Street pump, London, 1854.

A brewery in Broad Street employing 70 workmen was entirely exempt, but, having a well of its own, and allowances of malt liquor having been customarily made to the employees, it appeared likely that the proprietor was right in his belief that resort was never had to the Broad Street well.

It was quite otherwise in a carriage factory at No. 38 Broad Street, where about 200 workpeople were employed, two tubs of drinking water having been kept on the

premises and always filled from the Broad Street well. Among these employees, 18 died of cholera. Similar facts were elicited for other factories on the same street, all tending to show that in general those who drank the water from the Broad Street well suffered either from cholera or diarrhea, while those who did not drink that water escaped. The whole chain of evidence was made absolutely conclusive by several remarkable and striking cases in Snow's report like the following:

"A gentleman in delicate health was sent for from Brighton to see his brother at No. 6 Poland Street who was attacked with cholera and died in 12 hours, on the first of September. The gentleman arrived after his brother's death, and did not see the body. He only stayed about 20 minutes in the house, where he took a hasty and scanty luncheon of rump steak, taking with it a small tumbler of cold brandy and water, the water being from the Broad Street pump. He went to Pentonville, and was attacked with cholera on the evening of the following day, and died the next evening.

After John York's original drawings

Fig. 3-2. Asiatic cholera and the Broad Street well, London, 1854.

*W*, well; *D*, main drain of house no. 40; *v*<sup>1</sup> and *v*<sup>2</sup>, cellars under street; *C*, cesspool; *P*, privy

"The deaths of Mrs. E. and her niece, who drank the water from Broad Street at the West End, Hampstead, deserve especially to be noticed. I was informed by Mrs. E.'s son that his mother had not been in the neighborhood of Broad Street for many months. A cart went from Broad Street to West End every day, and it was

the custom to take out a large bottle of the water from the pump in Broad Street, she preferred it. The water was taken out on Thursday, the 31st of August, and she drank of it in the evening and also on Friday. She was seized with cholera on the evening of the latter day, and died on Saturday. A niece who was on a visit to this lady also drank of the water. She returned to her residence, a high and healthy part of Islington, was attacked with cholera, and died also. There was no cholera at this time, either at West End or in the neighborhood where the niece died. Besides these two persons only one servant partook of the water at West End, Hampstead, and she did not suffer, or, at least, not severely. She had diarrhea."

John York, Secretary and Surveyor of the Cholera Inquiry Committee, was instructed to survey the locality and examine the well, cesspool, and drains at No. 40 Broad Street (Sedgwick, 1902). His report revealed the following condition of affairs: The well was circular in section, 28 feet 10 inches deep, 6 feet in diameter, lined with brick, and when examined (April, 1855) contained 7 feet 6 inches of water. It was arched in at the top, dome fashion, and tightly closed at a level 3 feet 6 inches below the street by a cover occupying the crest of the dome. The bottom of the main drain of the house from No. 40 Broad Street lay 9 feet 2 inches above the water level, and one of its sides was distant from the brick lining of the well only 1 foot 8 inches. This was an old-fashioned drain 12 inches wide, with brick sides; the top and bottom were made with old stone. It had a small fall to the main sewer. The mortar joints of the old stone bottom were found to be perished, as was also the pointing of the brick sides, which had brought the brickwork into the condition of a sieve, through which the house drainage must have percolated for a considerable period. Snow found the cesspool intended for a trap, but misconstructed, and upon and over a part of the cesspool a common privy, without water supply, for the use of the house had been erected. The brickwork of the cesspool was found to be in the same decayed condition as the drain. Snow states that, "from the charged condition of the cesspool, the defective state of its brickwork, and also that of the drain, no doubt remains upon my mind that constant percolation, and for a considerable period, had been conveying fluid matter from the drains into the well. A washed appearance of the ground and gravel flow corroborated this assumption. The ground between the cesspool and the well was black, saturated, and in a swampy condition, clearly demonstrating the fact." This evidence, while only circumstantial, is sufficient to connect the cesspool with the well, and can leave no doubt in the minds of those who study this interesting and instructive instance that the water became infected with cholera germs through this channel. It should be remembered that this outbreak occurred before the days of bacteriology, so that direct proof is not at hand. As far as could be determined, the infection of the well came from an unrecognized case of cholera in the house at No. 40 Broad Street. There were 4 severer cases of cholera subsequently in the same house.

The Cholera Epidemic in Hamburg in 1892. This epidemic stands out clearly, not only as the most devastating of its kind, but as one of the most instructive. The relation between the infected water and the disease was conclusively proved, and the value of slow sand filtration placed upon a strong foundation. The conditions of the epidemic were equal to those of a well-controlled laboratory experiment, and the bacteriological and epidemiological evidence corroborated each other in every essential particular.

From August 17 to October 23, 1892, a little over two months, there were nearly 17,000 cases of cholera in Hamburg (population 640,000), with 8,065 deaths. On one day during the height of the epidemic over 1,000 new cases occurred. This was a pandemic year for cholera in the sense that it showed a remarkable tendency to spread to all parts of the world. It traveled from the valley of the Ganges through Persia, to Russia, Germany, Austria, France, Belgium, Holland, and the disease was brought to our own doors and several cases occurred in New York City.

The epidemic involved Hamburg, Altona and Wandsbeck. Hamburg and Altona are adjacent but separate cities. Hamburg, being an old Hanseatic city, had its own government. Altona, however, is in Prussia. Wandsbeck (population 20,000) is a nearby suburban town. Each of these three places at the time of the epidemic had a separate water system. Wandsbeck drank from an independent supply taken from

Fig. 3-3. Water Supply of Hamburg.

Hamburg received its water supply from the Elbe River (unfiltered) at G. The sewerage of Hamburg entered the Elbe at ABC. Altona received its water supply from the Elbe at D, about 8 miles below ABC. The sand filters which purified this water were located at Blankenese. Wandsbeck had an independent water supply from a small lake.

a small lake. Hamburg and Altona were both furnished with water from the Elbe River, which is a grossly polluted stream. Both the cities of Hamburg and Altona rest upon the bank of the Elbe River, but Altona is below or downstream. At the time of the epidemic the intake for the water supply of each city was directly at the river front, and the sewers of the city emptied into the river at various points along the same river fronts. It will, therefore, be seen that Altona had Elbe River water plus Hamburg's sewage. Altona, however, filtered this water by the slow sand process; Hamburg furnished its citizens with the raw, unfiltered Elbe River water. This water was first pumped to a single reservoir, which at one time held approximately a day's supply, but had long become inadequate. It will, therefore, be seen that these three cities, with a homogeneous population, with the same climate, the same low-lying site, and all other conditions similar, differed only in their water supplies.

Relatively few cases occurred in Altona, and most of these were on the boundary, where the people probably had access to Hamburg's raw, unfiltered Elbe River water. In Koch's own words, "cholera in Hamburg went right up to the boundary of Altona and there stopped. In one street, which for a long way forms the boundary, there was cholera on the Hamburg side, whereas the Altona side was free from it."

During the epidemic the deaths in the several cities were as shown in Table 3-2.

Table 3-2. Deaths and death rates from cholera in three cities in 1892

City	Population	Deaths	Deaths per 10,000 Inhabitants
Hamburg	640,400	8,605	134.4
Altona	143,000	328	23.0
Wandsbeck	20,000	43	22.0

Further evidence consisted in the fact that at one point close to and on the Hamburg side of the boundary line between Hamburg and Altona was a large yard known as the Hamburger Platz. It contained two rows of large and lofty dwellings containing 72 separate tenements and some 400 people belonging almost wholly to those classes who suffered most from cholera elsewhere in Hamburg. While cholera prevailed all around, no single case occurred among the many residents of this court during the whole epidemic. Koch found that, owing to local difficulties, water from the Hamburg mains could not easily be obtained for the dwellings in question, and hence a supply had been obtained from one of the Altona mains in an adjacent street. This was the only part of Hamburg that received Altona water, and it was also the only spot in Hamburg in which was aggregated a population of the class in question which escaped the cholera.

The source of the epidemic was traced to Russian immigrants crowded in barracks on one of the wharves pending their embarkation for the United States, and at the time of the outbreak there were on an average about 1,000 of these people on hand all the time. Many of them came from districts in Russia which had been, and were then, suffering severely from cholera, and all were well supplied with dirty clothing and blankets, some of which they washed while they were being detained. It is believed that among those that had arrived there must have been some mild cases of the disease, or at least some convalescents and carriers. All of the sewage matters of every description from these people were discharged directly into the river at the wharf. After the Elbe River once became seeded with the cholera vibrio the people in Hamburg who drank this infected water took the disease, and their discharges, returning to the river, added fuel to the flames. A vicious circle was thus set up, so that the infection became exceedingly concentrated and intense, and as the circle was a short one the time interval was correspondingly brief and the virulence unusually severe.

The Hamburg outbreak will ever remain classic on account of the clearness of the circumstances and the fact that there is no missing link in the chain of evidence as the specific organism was readily isolated from the Elbe River water. The conditions proved the effectiveness of filtering out cholera, and gave a greater impetus

to slow sand filtration, thus illustrating the saying that an epidemic may save more lives than it costs.

**OTHER MODES OF TRANSFERENCE.** In addition to the violent outbreaks, cholera occurs in nests or smolders like endemic typhoid. It is difficult to trace the connection between cases in endemic areas. Thus, a careful study of the cholera situation in Manila disclosed the fact that isolated cases would crop up at widely different points without any evident connection between them. Cholera carriers were suspected and later demonstrated. At irregular intervals of several years the disease would gather force, and cases multiply, until it assumed epidemic proportions, entirely independent, it is believed, of the water supply. The way cholera was dragged across our continent by the "forty-niners," and its occurrence among the Mecca pilgrims, are instances of its spread largely independent of infected water.

**CONTACT INFECTION.** Contact infection in cholera must not be underestimated. Persons frequently become infected through handling the dejecta or through freshly infected fomites, such as soiled linen. Direct transmission from person to person was formerly seen among physicians and nurses. In congested quarters, where many persons live under uncleanly conditions, contact infection plays an important part. The same thing may be seen on board vessels, in which case the disease may be confined to the firemen, stewards or some other limited group who are required to live in close contact with each other. Epidemic outbreaks due to contact infection have been recorded.

*Milk* may be contaminated, but is rarely a medium of infection because raw milk is not a common article of diet among the peoples living in countries where cholera prevails. Green vegetables and fruit that have been washed in an infected water may convey the disease.

**FLIES, ETC.** It has been shown that the cholera vibrios may live in the intestines of flies for at least three days, and these and other insects may also spread the infection mechanically. The cholera vibrio is a frail organism and dies rapidly when dried or exposed to light and other injurious influences. Infection through the air is, therefore, not to be dreaded. Fomites, such as bed and body linen or other objects, including spoons, dishes, toys, etc., contaminated with the discharges, can be regarded as possible sources of infection. There is, however, a special limitation in this case, owing to the fact that this organism is so readily destroyed by desiccation and crowded out by saprophytic micro-organisms. Thus, as a rule, only fresh dejecta and freshly contaminated objects are possible hazards.

**Immunity and Prophylactic Inoculation.** An attack of cholera does not necessarily confer protection against a subsequent attack. Nevertheless, second attacks within a period of a few years are uncommon. Attempts to immunize man with cholera vaccines were made by Ferran in Spain in 1884, and Haffkine in 1895. The latter used live avirulent cultures followed by virulent cultures. Reactions were so severe that the procedure soon fell into disfavor. Kolle showed that killed cultures were antigenically efficacious.

The vaccine approved by the Allied Armed Forces during World War II consisted of an 18-hour growth on infusion agar emulsified in sterile salt solution standardized to contain 8 thousand million vibrios per milliliter and killed by adding phenol to a final concentration of 0.5 per cent. The final product contains 4 thousand million Inaba and 4 thousand million Ogawa vibrios per milliliter in 0.5 per cent

phenol saline. On storage, autolysis may occur so that the vaccine becomes almost water clear; this does not interfere with its activity. It is given subcutaneously in two doses, the first 0.5 ml., the second 1 ml. after a ten-day interval. Reactions to these injections are analogous in severity to those sustained after inoculation with typhoid vaccine. The immunity conferred is thought to last less than a year so that a stimulating dose of 1 ml. should be given subcutaneously at six-month intervals to maintain protection continuously.

There is an extensive literature dealing with the protective value of various preparations of cholera vaccine in human populations under conditions of natural exposure. In general, the consensus of opinion has been that it is of value, although this judgment is rendered uncertain by lack of comparability of the inoculated and uninoculated groups. In a recent study made in India (Adishesan and others, 1947), the carefully analyzed evidence indicated that a single dose of the vaccine used reduced the risk of a clinical attack, but did not change the case fatality from cholera. The attack rate in the uninoculated population was found to be two and one-half times greater than that in the inoculated population under conditions of comparable exposure.

**International Quarantine.** International cooperation in public health and sanitary matters took its origin in the efforts to prevent spread of epidemics of cholera and plague from the East to the European countries. The practice of maritime quarantine has become increasingly effective during the past century as one country after another has organized a system of inspection, detention and disinfection of ships, aircraft and other common carriers at the port of arrival. Cholera is particularly amenable to quarantine measures. It has a short incubation period. Passengers coming from an infected local area or who have been in contact with a suspected case may be placed under surveillance for a period of not more than five days. The onset of the disease is abrupt and the clinical course is short, ending in recovery or death within a few days. The diagnosis can be accurately and rapidly confirmed by laboratory procedures and the carrier state is relatively short. Detention and quarantine of convalescents and carriers is ordinarily not prolonged. International Sanitary Regulations now in force are those adopted by WHO (1951). The possession of a valid certificate of vaccination against cholera is taken into consideration by the health authority in applying measures provided for in the regulations.

**Community Control.** In those areas of the world, particularly southeast Asia where the disease still occurs, principal reliance is placed upon mass immunization with cholera vaccines to control epidemics. Prevention of epidemics and reduction of the endemic prevalence of the disease can be accomplished only by improving the conditions of living in regard to water supply, fecal disposal and home and personal hygiene. Only a little improvement in the level of sanitation may be required to have a decided effect.

Scrupulous cleanliness on the part of the person and his surroundings is required. Those who handle cholera patients, their dejecta, or infected articles must carefully disinfect their hands each time and should under no circumstances eat or drink anything in the sick room. During cholera times all water and food of every description should be boiled or thoroughly cooked just before it is eaten. Great care must be exercised that the water or food does not become infected after it has been boiled or cooked.

## TYPHOID FEVER

Typhoid fever was confused for centuries with other continued fevers, such as recurrent fever, septic infections and typhus fever. The first full description of what was probably typhoid fever was written by Thomas Willis, an English physician, who, in 1643, described an epidemic that occurred in Parliamentary troops. Bretonneau, in 1826, further described the clinical characteristics and called it "dothienenteritis," or abscess of the small intestine, a name it frequently bears in French literature. Louis, the distinguished French clinician, in 1829 gave the name typhoid fever to the malady to distinguish it from typhus fever. In 1836, William Gerhard, of Philadelphia, a pupil of Louis, showed the difference in the lesions between these two fevers, which established typhoid fever as a distinct disease, but it was not until after the middle of the nineteenth century that the disease became widely known under this name in the United States, even to the medical profession.

William Budd, in 1856, pointed out that the disease is transmitted by the patient's excreta. He stated that: "The living human body, therefore, is the soil in which this specific poison breeds and multiplies." The first water-borne outbreaks carefully studied and described was at Lausen, Switzerland, in 1872; the first water-borne outbreak to attract attention in the United States occurred in Plymouth, Pennsylvania, in 1885. In 1875, Murchison traced an epidemic to a contaminated milk supply. Eberth, in 1880, saw the *Bacillus typhosus* in the tissues, and four years later Gaffky grew it in pure culture. Metchnikoff and Besredka, in 1900, finally established the etiological relationship by producing the disease in anthropoid apes with pure cultures. In 1894, Pfeiffer and Kolle first gave small subcutaneous inoculations of dead typhoid bacilli. About the same time, and independently, A. E. Wright began similar inoculations in British soldiers.

Occurrence. Typhoid fever has a world-wide distribution. It is endemic almost everywhere but the level of prevalence varies within wide limits both geographically and in relation to time. With the industrial revolution and the tendency of populations to congregate in cities during the eighteenth and nineteenth centuries, it became

major pestilence in Western Europe and in North America. In many countries is still a public health problem of great importance.

In cities of the United States, death rates of more than 50 per 100,000 were not uncommon and in a few the figure was over a hundred. Prevalence was correspondingly high in the smaller towns and rural districts of the country but during this period somewhat lower than the adjacent urban areas. In the U. S. Registration Area as a whole, typhoid fever was fourth among the communicable diseases as a cause of mortality. In 1900, the death rate was 31.3 per 100,000 population. From that figure it has decreased steadily until in 1948 the rate was 0.2 per 100,000. Recent urban experience is indicated in the accompanying table. It is apparent that in some parts of the country the progress has been more rapid than in others. The downward trend in the cities was paralleled by a downward trend in the rural areas but these lagged behind somewhat so that the disease is now more rural than urban. In some states the higher rates persisted in the smaller towns and villages rather than in the isolated country districts (Leach and Maxcy, 1926). The disease has practically disappeared from large areas in the northern part of the country.

Table 3-3. Total typhoid death rate per hundred thousand of population for ninety-three cities according to geographic divisions

	Population *	Typhoid Deaths			Typhoid Death Rates

**Military Experience.** During the wars of the eighteenth and nineteenth centuries, typhoid was ranked with typhus, plague, dysentery, cholera and smallpox as one of the principal causes of mortality and morbidity in military populations. An extreme example of what happened is presented in the report on the origin and spread of typhoid fever in the U. S. military camps during the Spanish-American War of 1898 (Reed and others, 1904). Among 107,973 officers and men in the National encampment, 20,748 had typhoid fever, an attack rate of 19 per cent, and there were 1,580 deaths. Following this report, the importance of military sanitation was realized and gradually adequate provision was made in Army organizations for the application of measures of sanitation in the field.

In 1911, the use of prophylactic typhoid vaccination became compulsory; this has continued with some changes in the vaccine preparation. The combined effect of improvement in sanitation in the civil and military population of the United States and of vaccination of Army personnel is indicated in Figure 3-4 (Holt, 1948).

Fig. 3-5. Seasonal distribution of deaths from typhoid fever in 16 cities in Ohio river basin, 1910-1914.

**Seasonal Distribution.** The seasonal distribution of typhoid fever is indicated in Figure 3-5. In those areas where dissemination by a common water supply is not an important factor, cases occur throughout the year, but are at a minimum during the winter and spring months, rising to a peak in the late summer and early fall. This is generally considered to be the characteristic curve for enteric infections. This distribution is disturbed, however, in those areas where pollution of common water supplies plays a role. Widespread epidemics of water-borne typhoid fever are not unusual in the coldest weather. The explanation for this difference in seasonal distribution is not clear, but there is some reason to believe that typhoid bacilli survive longer in surface water during the colder than during the warmer months of the year.

**Age and Sex.** Where exposure is equal, typhoid fever attacks one sex as readily as the other. It is common experience, however, to find in morbidity and mortality statistics derived from large populations, over long periods of time, that there are more cases among males than females at all ages. This sex difference has been attributed to the fact that the male is apt to be more gregarious and range more widely in his activities, and thus suffers a greater exposure.

Age selection is characteristic and is indicated by the accompanying table showing the mean annual age specific typhoid morbidity rates for New York State, 1928-1932. The disease is less frequently recognized in children under five years and

Table 3-4. Mean annual age-specific typhoid morbidity rates for New York State, exclusive of New York City, 1928-1932

Age Group	Population 1930 Census	Number of Cases	Mean Annual Morbidity Rate per 100,000
0-4	382,871	29	7.6
5-9	428,742	81	18.9
10-19	816,144	161	19.7
20-29	725,476	117	16.1
30-over	2,399,172	209	8.7
TOTAL	4,752,405	597	12.6

From Ramsey, G. H., *Am. J. Hyg.*, 21:665, 1935.

appears to run a somewhat milder course. The highest attack rates are suffered by adolescents and young adults. In older ages the attack rate decreases progressively; this is probably due in part to acquired immunity.

**Period of Incubation.** In epidemics due to transmission by a common vehicle it is frequently possible to fix the time of exposure quite definitely. Since in many individuals the onset of the disease is insidious it is not always equally easy to fix the time of onset. A range of 7 to 21 days encompasses the incubation period for the great majority of cases, the average is about 14 days, and the extremes are 3 to 38 days. It has been suggested that in epidemics transmitted by food, where the dosage is presumably large, the incubation period may be shorter than in water-borne outbreaks where the dosage is presumably small. The validity of this generalization has been questioned.

**The Disease.** The disease is a generalized infection characterized by a continued fever lasting about four weeks. The onset is usually insidious beginning with malaise, anorexia and headache. The temperature rises in a step-like manner to an average of about 104° F, with a pulse rate that tends to be slow in comparison with the height of the fever. During the first week, the patient usually becomes prostrate, nose bleeds are frequent. A diarrhea develops, though constipation is sometimes present, either condition being accompanied by some degree of abdominal tenderness and distension. During the first part of the illness discrete rose-colored spots may be seen scattered over the trunk. The spleen is enlarged. In the more severe cases as time passes the patient may become stuporous or delirious. After the third week the temperature curve begins to show morning remissions and gradually returns to normal by lysis. A leukopenia is present in most cases.

**Pathogenesis.** Typhoid bacilli enter the body through the alimentary tract. They localize and multiply during the incubation period in the lymphoid tissue of the wall of the small intestine and regional lymph nodes. Here micro-organisms may be seen within plasma cells. From this site they enter the blood stream via the lymphatics and thoracic duct. As the defensive mechanism comes into play, endotoxin is produced, causing some of the symptoms of the disease. The micro-organisms localize particularly in the spleen and bone marrow. The gallbladder is invariably infected. Occasionally there is some bronchopneumonia. The involvement of the lymph nodes in the intestines may lead to ulceration and intestinal hemorrhage or perforation. These are serious and often fatal complications. In about 10 per cent of cases after the temperature has returned to normal, a relapse of variable duration occurs. The case fatality rate, based upon clinically recognized and reported cases, has usually been about 10 per cent in the past. Under modern treatment with proper attention to dietary and fluid balance, and with judicious use of antibiotic drugs—aureomycin and chloromycetin—convalescence is shortened. It is not yet clear what effect this has upon the risk of complications, relapse and death.

**Laboratory Diagnosis.** Typhoid bacilli appear in the blood early in the disease; perhaps occasionally during the prodromal symptoms. Kayser obtained positive blood cultures from about 90 per cent of patients during the first week of illness, 65 per cent in the second, 42 per cent in the third and 35 per cent in the fourth. With defervescence the blood cultures become negative but in the event of relapse micro-organisms may reappear in the blood stream. Recovery and identification of *S. typhosa* from blood cultures definitely establishes the diagnosis of typhoid fever.

The bacilli leave the body in feces and urine and occasionally in the sputum and other discharges during the acute illness and for a variable time during convalescence or relapse. The most reliable laboratory test is the isolation of the etiological organism from feces. The frequency with which typhoid organisms can be demonstrated in fecal specimens has been considerably increased by modern bacteriological technique, particularly by employment of selective and enrichment fluid media, such as peptone tetrathionate, and by selective plating media, such as bismuth sulphite agar (Diagnostic Procedures and Reagents, 1950). Repeated examination of specimens is essential, but with proper specimens and bacteriological methods the causative organism can be demonstrated in a great majority of cases at some time during the illness. With defervescence and the establishment of convalescence the frequency of positive stools and urine cultures rapidly decreases.

Formerly a great deal of dependence was placed upon the demonstration of agglutinins in significant titers in the blood serum of the patient, the Widal reaction. It was found that usually, but not always, agglutinins appeared in the blood from between the third and seventh day of the disease, rose at first slowly and then more steeply to a maximum between the sixteenth and twenty-seventh days and then fell slowly so that they were detected for weeks or months after convalescence.

As the antigenic structure of different species of the *Salmonella* group of micro-organisms was elucidated, it became apparent that the interpretation of this agglutination test was not as simple as had been at first thought. It was found that during any febrile illness, agglutinins for *S. typhosa* might appear in the blood as a result of some previous experience with a related organism in the *Salmonella* group or as a result of previous typhoid vaccination. This technical difficulty was partially overcome by Felix and others who showed that a distinction must be made between the development of O (somatic) agglutinins and H (flagellar) agglutinins. It is now routine to test sera against both the formalin-treated or other suspension of *S. typhosa* which has been shown to be satisfactory to demonstrate the flagellar or H type of agglutinins, and the alcohol-treated or other suspension of *S. typhosa* suitable for the demonstration of the granular or O type agglutination. The results of these agglutination tests are to be interpreted by the physician only with a full knowledge of the history of the patient, especially with reference to previous vaccination against typhoid fever. Repetition of the test with standardized reagents should be made in order to secure an index of rise or fall of the agglutinin titer. Only when high titers (O, 1:500 or H, 1:1,000) are reached does the test approach diagnostic value where evidence from repeated attempts to recover the causative micro-organism by culture have failed.

In 1934, Felix and Pitt found that smooth strains of typhoid bacilli differed very widely in regard to their sensitiveness to agglutination by an O antiserum, and that this sensitivity was inversely related to virulence of the strains as judged by the intraperitoneal injection of mice. They showed that this was due to the presence of a special antigenic component which Felix called "Vi" antigen. Human serum may be tested for Vi antibody by employing a living suspension of a pure Vi strain of *S. typhosa*. The presence of Vi antibodies in the human serum is indicative of active infection and useful in the detection of carriers (Felix, 1938).

As soon as the special importance of the so-called Vi antigen of typhoid bacillus was recognized, a number of investigators working independently in different countries established the existence of bacteriophages which were specific for the Vi form of typhoid bacillus. These 'phages attack typhoid strains irrespective of their origin, provided the cultures contain adequate quantity of Vi antigen. By propagating a particular anti-Vi 'phage on typhoid strains isolated from different sources, Craigie and Yen (1938) obtained bacteriophages which had developed a high degree of specificity for the particular strain in which they were grown. When such adapted 'phage preparations were tested against a number of typhoid strains from different localities, it was found that the strains could be divided according to their response to the different 'phage preparations and that strains that were related epidemiologically belonged to the same 'phage type. For use in routine typing a variable number of standard 'phage preparations are recommended. The types are designated by letters of the alphabet and by an added numerical subscript. The types found vary

in different geographic areas (Felix, 1943; Olitski and Shelubsky, 1945; Morris and others, 1945; Crocker, 1947). This procedure has been found of practical value in tracing the sources of small outbreaks of typhoid fever. It can be assumed that cases infected from the same source will be found to have the same Vi phage type of typhoid bacillus. When the epidemiological evidence appears to incriminate a chronic carrier, it can be shown that the carrier is harboring the same Vi phage type as that isolated from the patient.

**Missed Cases and Carriers.** An interesting outbreak of typhoid fever in a population exposed to a contaminated industrial supply was reported by Murphy and others (1944). It occurred in a small mill village with a population of approximately 721. Of these, 701 were kept under observation by the investigators, questioned with regard to the occurrence of clinical symptoms of typhoid and stool specimens obtained from 642. Eighty of these 642 specimens were positive for *S. typhosa*. Thirty-eight were from patients confined to bed for 10 days or more, and 20 from one to nine days. Eleven of those who had positive stools were ambulatory at all times and in 11 more there was no history of illness. Two of the latter became chronic carriers. Little more than one half of the 69 cases with symptoms were treated by physicians; several others were discovered through the efforts of the health authorities; 23 additional cases, as well as 11 asymptomatic infections, were discovered through a house-to-house canvass. This illustrates the fact that where careful studies are made during a typhoid outbreak the organism is more widely distributed in the population than would be indicated from the occurrence of cases which are diagnosed and reported by physicians.

At least 50 per cent of cases continue to discharge typhoid bacilli in their feces for three weeks after the onset of the disease, and about 5 per cent are still discharging the organisms after 11 to 13 weeks. At the end of five months, the figure has decreased to about 3 per cent. These are known as *convalescent carriers*. A *chronic carrier* is a person who has not suffered from typhoid fever within the previous 12 months and who discharges typhoid bacilli—in other words, individuals who may or may not have had a clinically recognized attack of typhoid fever but who continue to excrete the organism over a period of at least one year. Those who harbor the organism without having had a clinically recognized attack are sometimes called *healthy carriers*.

The frequency of the carrier state in relation to age and sex is indicated by the accompanying table. These data are in accord with general experience in this regard. Older persons are more likely to become carriers than children; there are more females than males; the highest frequency is found in females aged 40-49. These facts are helpful in epidemiological investigations directed toward finding a carrier.

With the data available from the experience of New York State and making certain reasonable assumptions, Ames and Robbins estimated that as of January 1, 1940, there were, in a total population of 5,952,000, approximately 2,490 carriers, or a carrier prevalence rate of 41.8 per 100,000. At this time there were under supervision of the State Department of Health only 419 known carriers, or about 16 per cent of the estimated total number. The carrier prevalence rate varies in different populations according to the past and current level of prevalence of typhoid.

Most of the outbreaks of typhoid fever traced to carriers turn out to be due to individuals who discharge typhoid bacilli in the feces rather than in the urine. Some

carriers are more dangerous than others. This is due partly to personal habits, partly to the opportunity to infect food and drink, partly to virulence and number of organisms discharged. Further, carriers are intermittent or irregular in the elimination of typhoid bacilli. Typhoid carriers in dairies have been responsible for many outbreaks; a carrier employed as a cook, waiter or a nurse in a dairy is a special menace. The amount of harm which a single individual can cause is amazing.

Table 3-5. Typhoid cases and resulting chronic carriers by age and sex in New York State, exclusive of New York City and state institutions, 1930-1939

Age at Time of Typhoid	Number of Cases		Number of Carriers		Per Cent of Cases Resulting in Carriers		
	M	F	M	F	M	F	Both Sexes
Under 10	347	281	2	—	0.6	—	0.3
10-19	491	411	2	1	0.4	0.2	0.3

40-49	173	122	6	20	3.5	16.4	8.8
50-59	110	78	10	9	9.1	11.5	10.1
60 and over	65	64	4	6	6.2	9.4	7.8
TOTAL	1,743	1,387	37	53	2.1	3.8	2.9

From Ames, W. R., and Robbins, M., Am. J. Pub. Health, 33:221, 1943.

The story of *Typhoid Mary* was the first of its kind to be reported in America, and it has become a classic. Mary Mallon was a cook in a family for three years, and in 1901 she developed typhoid fever. About the same time a visitor to the family had the disease. One month later the laundress in this family was taken ill.

In 1902, Mary obtained a new place, and two weeks after her arrival the laundress was taken ill with typhoid fever. In a week, a second case developed, and soon seven members of the household were sick.

In 1904, the cook went to a home on Long Island. There were four in the family, besides seven servants. Within three weeks after her arrival, four servants were attacked.

In 1906, Mary went to another family, and six of the 11 members of this family were attacked with typhoid between August 27 and September 3. At this time, the cook was first suspected. She entered another family on September 21, and on October 5 the laundress developed typhoid fever.

In 1907, she entered a home in New York City and two months after her arrival two cases developed, one of which proved fatal. During these five years, "Typhoid Mary" is known to have been the cause of 26 cases of typhoid fever.

She was virtually imprisoned by the New York Department of Health in a hospital from March 19, 1907. Cultures taken every few days showed bacilli on and off for three years. Sometimes the stools contained enormous numbers of typhoid bacilli, and again for days none could be found.

"Typhoid Mary" then escaped from observation until 1914. In October of that

year, she was engaged as cook in the Sloane Hospital for Women in New York. In January and February of 1915, an outbreak of typhoid occurred, principally among the doctors, nurses and help of the institution, involving 25 cases. The cook was suspected, but she left the premises on a few hours' leave, and did not return or leave her address. She was, however, located by the Health Department under an assumed name, and an investigation established her identity as the famous "Typhoid Mary."

A subsequent study of her career showed that she had infected still other individuals beyond those already mentioned, and that she may have given rise to the well-known water-borne outbreak of typhoid in Ithaca, New York, in 1903, involving over 1,300 cases. The fact is that a person by the name of Mary Mallon had been employed as a cook in the vicinity of the place where the first case appeared, and from which contamination of the water supply occurred.

**OTHER EXAMPLES.** Sawyer (1915) reported a very instructive history of a typhoid carrier (H. O.) responsible for several outbreaks. The carrier was carefully studied over a period of several years, during which time he infected 30 persons, five of whom died. Frequent examinations of feces of this carrier gave negative results for four months after he had been treated with autogenous typhoid vaccines; nevertheless, he infected three persons when subsequently released from quarantine on parole. The removal of the gallbladder failed to cure H. O., for typhoid bacilli were found in the feces several times after the operation. It is particularly noteworthy that 41 successive examinations of feces during a period of 14 months all proved negative, yet the typhoid bacillus was finally isolated from the stomach contents containing bile. This carrier, on account of the virulence of the organism, or careless personal habits, is unusually dangerous and represents a class that should be controlled by quarantine or close supervision.

Another instructive outbreak occurred in Hanford, California, in which 93 cases of typhoid fever resulted from a large pan of spaghetti prepared by a carrier and served at a public dinner (Sawyer, 1914). This dish was baked after it had been infected, but this baking was shown by laboratory experiments to have incubated the bacteria in the center of the mass.

**Control of Carriers.** As typhoid decreases to a low level of prevalence with improved sanitation, discovery and supervision of carriers becomes increasingly important. A typhoid carrier register is gradually accumulated through information gained from various sources. The principal methods of discovery are through follow-up of current cases during convalescence with periodic stool and urine examinations, and through epidemiological investigations tracing the sources of small groups of sporadic cases, delimiting endemic foci. Rarely are carriers discovered by routine examination of stool specimens of persons working as food-handlers. Occasionally one is picked up by the routine examination of bile from gallbladders removed in cholecystectomy. As they are discovered, the carriers are placed under supervision either voluntarily or by legal compulsion. Thereafter, they should be visited twice a year by the appropriate health official. With proper care and cleanliness they may present little danger to their fellowmen. However, this requires proper instruction and intelligent cooperation. Each carrier should be instructed with regard to personal hygiene and prohibited from preparing food for any person except members of his own household who have been vaccinated against

typhoid fever within two years. It is particularly important that all convalescent and chronic carriers be prohibited by law from preparing food for the public, including the handling of milk and milk products on farms or in milk plants (Committee on Administrative Practice, 1949).

It is unusual to find an exception to the rule that chronic carriers will be carriers for the rest of their lives, unless the focus of infection be removed by operation. No drug or antibiotic (including aureomycin and chloromycetin) has yet been found which will cure the chronic carrier state. Only a few spontaneous cures without operation have been recorded.

Removal of the gallbladder for the cure of chronic typhoid carriers should be advised only after careful consideration of the physical condition and age (under 60 years) of the carrier and should not be advised unless preliminary duodenal specimens show the presence of typhoid bacilli in the bile. A typhoid carrier who has had his gallbladder removed will often continue to excrete typhoid bacilli for several days, and in some instances for from one to six months after the operation. When the stool specimens become negative, monthly specimens should be obtained until 12 months have elapsed since the first negative specimen. Final release should depend upon the failure to find typhoid bacilli in the bile obtained by duodenal tube, and examination of the next two stool specimens after giving magnesium sulphate through the duodenal tube. In the State of Massachusetts (Bigelow and Anderson, 1933), this operation is done at the public health expense; this is cheaper and more effective than subsidies. Senftner and Coughlin (1933), reviewing the experience of New York State, found that in 68 persons operated on, excluding those with gallbladder symptoms, the mortality was 3.7 per cent. Of those who survived the operation, 68 per cent were apparently cured of the carrier condition.

**Resistance of the Bacillus.** The typhoid bacillus has no spore. It is, therefore, comparatively easy to destroy. The only difficulty presenting itself is getting at the bacillus when imbedded in fecal masses. When dry, most typhoid bacilli die in a few hours; occasionally a few survive for months. The fact that most typhoid bacilli are killed by drying renders infection through dust unlikely.

In a moist medium, such as water, milk, or urine, typhoid bacilli are killed at 60° C in 20 minutes. They are not destroyed by freezing.

In their resistance to germicides typhoid bacilli behave like the average nonspore-bearing bacilli. Thus, bichloride of mercury, 1:1,000; phenol 2.5 per cent; formaldehyde solution, 10 per cent, are effective upon the naked germs. In order to kill the typhoid bacilli in feces, special precautions, longer exposures or stronger solutions are necessary (see page 204).

The viability of typhoid bacilli in feces is very variable, depending on the composition of the feces and the varieties of other bacteria present. Sometimes the typhoid bacilli in feces perish in a few hours, often in a day; under certain circumstances they may live for much longer periods. Levy and Kayser found that they may remain alive in feces for five months in the winter. The life of the organism in privies and in water is usually comparatively short. In nature they seldom, if ever, live in water beyond seven days, and are often dead in 48 hours. They probably live longer in clean water than in contaminated water; in cold water than warm water. In the outer world, antibiosis plays an important part, also the presence of deleterious chemicals, temperature, sunlight, and other factors known to be injurious to

spore-free bacteria. As a rule, the typhoid bacillus does not survive long in the soil under the usual conditions.

The typhoid bacillus may live 12 days in crude sewage (Firth); 14 days in a septic tank (Pickard); four months in butter (Balley and Field); five days in home-made cheese (Heim); 12 days in pot cheese (Lemke); 39 days in ice cream (Mitchell). These are maxima. It is destroyed in 24 hours in milk, buttermilk, whey or butter having an acidity of 0.3 to 0.4 per cent. Krumwiede and Noble found that with a moderate contamination, typhoid bacilli are killed in sour cream in approximately four days.

The typhoid bacillus is an obligate human parasite. It lives and grows principally in the human body. It has a tendency to die in water, air, soil, upon fomites, or in nature generally in a comparatively short time except under special circumstances as in the case of milk, in which it grows well. The ultimate sources of all typhoid infections are patients, missed cases and carriers.

**Transmission.** Transmission may be rather direct by contaminated fingers to food, i.e., by "contact," or indirect through water, milk, milk products, oysters or other foods, i.e., by a common vehicle.

**Water-Borne Typhoid.** Water-borne typhoid is a common occurrence. Not long ago it was regarded as the sole or usual mode of spread; now we know that this was a mistake. Most fecal matter ultimately finds its way to water; most water courses draining inhabited regions are contaminated with human feces. Surface water is, therefore, apt to contain typhoid bacilli. The fact that there may be no clinical case of typhoid fever in the drainage area is no guarantee that the water may not be infected—in view of the prevalence of missed cases and bacillus carriers.

Fortunately, typhoid bacilli do not grow and multiply in water under natural conditions. They usually die in a few days, and rarely persist longer than seven days. They succumb more quickly in some waters than others, more quickly in summer than winter. Ruediger (1911) has shown that typhoid bacilli disappear much more rapidly from polluted water during the summer months than during the winter months when the river is protected with a covering of ice and snow.

Water plays a large but diminishing role in the spread of typhoid fever, on account of filtration, chlorination and sanitary control of water supplies. The great water-borne epidemics have overshadowed the other modes of communication. Whipple, in 1908, estimated that 35 per cent of the typhoid in this country was water-borne; now it occurs only occasionally.

In the vast majority of cases, water-borne typhoid is contracted from a surface supply; that is, a river, small stream, pond or lake. Ground water becomes a source of danger only under special conditions, especially in limestone regions. Bathing in polluted water is an occasional cause.

#### HISTORICAL EPIDEMICS DUE TO POLLUTED WATER SUPPLIES

**The Typhoid Epidemic at Lausen, Switzerland.** The epidemic of typhoid fever which occurred in Lausen, Switzerland, in 1872, was the first to attract general attention, "and, because of certain peculiar conditions connected with it, and especially because of its influence upon the theory and practice of the purification of water by filtration, it deserves the most careful consideration by all students of sanitation." It is also interesting because of the remoteness and unusual method by

which the infection reached the water supply. The following account of this epidemic is from the description by Sedgwick, quoting Hagler's report:

The epidemic occurred in the little village of Lausen in the canton of Basel in Switzerland in August, 1872. Lausen was a well-kept village of 90 houses and 780 inhabitants, and had never, so far as known, suffered from a typhoid epidemic. For many years it had not had even a single case of typhoid fever, and it had escaped cholera even when the surrounding country suffered from it. Suddenly, in August, 1872, an outbreak of typhoid fever occurred, affecting a large part of the entire population.

A short distance south of Lausen is a little valley, the Fürlethal, separated from Lausen by a hill, the Stockhalden, and in this valley, on June 19, upon an isolated farm, a peasant, who had recently been away from home, fell ill with a severe case of typhoid fever, which he had apparently contracted during his absence. In the next two months there occurred three other cases in the neighborhood—a girl, and the wife and son of the peasant.

No one in Lausen knew anything of these cases in the remote and lonely valley, when suddenly, on August 7, 10 cases of typhoid fever appeared in Lausen, and by the end of nine days 57 cases. The number rose in the first four weeks to more than 100, and by the end of the epidemic in October to about 130, or 17 per cent of the population. Besides these, 14 children who had spent their summer vacation in Lausen fell ill with the same disease in Basel. The fever was distributed quite evenly throughout the town, with the exception of certain houses which derived their water from their own wells and not from the public water supply. Attention was thus fixed upon the latter, which was obtained from a well at the foot of the Stockhalden hill on the Lausen side. The well was walled up, covered, and apparently protected, and from it the water was conducted to the village, where it was distributed by several public fountains. Only six houses used their own wells, and in these six there was not a single case of typhoid fever, while in almost all the other houses of the village, which depended upon the public water supply, cases of the disease existed. Suspicion was thus directed to the water supply as the source of the typhoid, largely because no other source could well be imagined.

There had long been a belief that the Lausen well or spring was fed by and had a subterranean connection with a brook (the Fürler brook) in the neighboring Fürler valley; and since this brook ran near the peasant's house and was known to have been freely polluted by the excreta of the typhoid fever patients, absolute proofs of the connection between the well of Lausen and the Fürler brook could not fail to be highly suggestive and important. Fortunately, such proofs were not far to seek. Some 10 years before observations had been made which had shown an intimate connection between the brook and the well. At that time, without any known reason, there had suddenly appeared near the brook in the Fürler valley below the hamlet a hole about eight feet deep and three feet in diameter, at the bottom of which a considerable quantity of clear water was flowing. As an experiment the water of the little Fürler brook was at that time turned into this hole, with the result that it had all flowed away underground and disappeared, and an hour or two later the public fountains at Lausen, which, on account of the dry weather prevailing at the time, were not running, had begun flowing abundantly. The water from them, which was at first turbid, later became clear; and it had continued to

flow freely until the Fűrler brook was returned to its original bed and the hole had been filled up. But every year afterward, whenever the meadows below the site of the hole were irrigated, or overflowed, by the waters of the brook, the Lausen fountains soon began to flow more freely. In the epidemic year (1872) the meadows had been overflowed as usual from the middle to the end of July, which was the very time when the brook had been infected by the excrements of the typhoid patients. The water supply of Lausen had increased as usual, had been turbid at the beginning, and had had a disagreeable taste. And about three weeks after the beginning of the irrigation of the Fűrler meadows typhoid fever had broken out, suddenly and violently, in Lausen.

In order to make matters more certain, if possible, the following experiments were made, but unfortunately not until the end of August when the water of the Lausen supply had again become clear. The hole which had appeared 10 years earlier, and had afterward been filled up, was reopened, and the little brook was once more led into it; three hours later the Lausen fountains were yielding double their usual volume. A quantity of brine containing about 18 hundred pounds of common salt was now poured into the brook as it entered the hole, whereupon there appeared very soon in the Lausen water first a small, later a considerable, and finally a very strong reaction for chloride, while the total solids increased to an amount three times as great as before the brine was added. In another experiment 5,000 pounds of flour (Mehl), finely ground, were likewise added to the brook as it disappeared in the hole; but this time there was no increase of the total solids, nor were any starch grains detected in the Lausen water.

It was naturally concluded from these experiments that while the water of the brook undoubtedly passed through to Lausen and carried with it salts in solution, it nevertheless underwent a filtration which forbade the passage of suspended matters as large as starch grains. Hagler, from whose report the foregoing facts are taken, was careful, however, to state that "it is not denied that small organized particles, such as typhoid fever germs, may nevertheless have been able to find a passage." As a matter of fact Hagler's minute account does today give us some indication that such germs might easily have passed from the brook to Lausen, for the turbidity of which he repeatedly speaks is evidence of the passage of particles as small as, and possibly smaller than, the germs of typhoid fever.

Unfortunately, this was before pure cultures of bacteria were known, and no experiments were made with suspended matters as small as bacteria. The conclusion was inevitable that although filtration had in this case sufficed to remove starch grains, it had been powerless to remove the germs of typhoid fever; and, accordingly, filtration as a safeguard against disease in drinking water fell for a time into disrepute.

**The Typhoid Epidemic in Plymouth, Pennsylvania.** In 1885, the mining town of Plymouth, Pennsylvania, with a population of about 8,000, suffered from a severe outbreak of typhoid fever which involved one in every eight of the inhabitants. Plymouth received its water from a mountain brook which drained an almost uninhabited watershed. The stream was dammed at intervals and the water was stored in a series of four small impounding reservoirs. The source of the infection was traced to a citizen who spent his Christmas holidays in Philadelphia and returned home in January. He contracted typhoid, the excreta were not disinfected, but were

thrown either into the frozen creek or upon its banks within 25 or 30 feet of the edge of the stream (see Fig. 3-6). At this time the brook was frozen and remained so until spring. There came a thaw in March and the entire accumulation was washed into the brook and thence into the water-main. Three weeks thereafter cases of typhoid by the score made their appearance throughout the town. On some days more than 100 new cases occurred. In all, 1,004 cases were reported. Some estimates placed the number at 1,500, that is, 1 in every 5 of the inhabitants. There were 114 deaths. The epidemic was limited to the houses supplied with the town water or to persons who drank of the public water supply. The distinction was particularly emphasized on one street where the houses on one side had one or more cases while the houses on the other side had none at all. The former were supplied by the polluted town water, while the latter depended upon wells.

Fig. 3-6. Typhoid epidemic in Plymouth, Pennsylvania, in 1885.

This epidemic teaches the lesson that one person is sufficient to defile the "pure waters of a mountain brook draining an almost uninhabited territory." Laboratory analysis of this water prior to the thaw would not have disclosed danger, but the hazard would have been discovered by a sanitary survey. This epidemic was the first large outbreak in America where the cause was definitely traced to the water supply. It stands out sharply in the sanitary annals of our country on account of the lessons it taught and the good influence it had in stimulating other cities to safeguard and improve their water supplies.

The Typhoid Epidemic at Ashland, Wisconsin. This outbreak is cited from Harrington and is one of peculiar interest, in that, in addition to serving as an excellent illustration of the danger of using the same body of water as a place for

the disposal of sewage and as a source of drinking water, it was made the basis of an action at law, which established the liability of water companies and municipalities in case of sickness and death caused by the distribution and use of infected water.

The city's supply was derived from an arm of Lake Superior, Chequamegon Bay, upon which the city is situated. This bay, which is about 12 miles long, and has an average width of five miles, varies from 8 to 36 feet in depth. North of the city, and extending outward in a northwesterly direction, is a breakwater constructed for the protection of the harbor against northerly gales. The mouth of the water intake was located about a mile from the shore between the breakwater and the city (see Fig. 3-7). The sewage of the city was discharged further to the west and south. The currents in the bay followed the course indicated by the arrows in the figure, and carried the sewage toward the breakwater and over the mouth of the intake. This condition of affairs was brought to the attention of the company by the health boards of the city and state repeatedly, but without results. That the water was polluted was evident on mere ocular inspection, for it was often cloudy or markedly turbid. During the winter of 1893-1894 typhoid fever made its appearance in the city, and from the initial cases a disastrous epidemic developed, which led to the establishment of a model filtering plant.

The action at law referred to above was brought by the widow of one of the victims. In evidence it was shown that he lived continuously in Ashland, and drank no water other than that supplied by the water company; that previous to his sickness the disease had prevailed in the city, and that the discharges from the antecedent cases had passed into the waters of the bay by way of the city sewers. The court found for the plaintiff in the sum of \$5,000.

**The Typhoid Epidemic in Mankato, Minnesota.** Mankato (population 11,553) received its water supply from four deep artesian wells on Washington Street. Two of these wells were within from 16 to 18 feet of the pumping station. The main outlet of the sewer was at Washington Street, emptying into the river. A great flood occurred May 20 to 24, 1908. The gate in the main trunk of the sewer was let down on the night of June 24, 1908, in order to keep the river from backing up into the sewers. This caused a backing up or stasis of the sewage, which in turn backed up into a well pit of the new artesian well near the pumping station, hence sewage was pumped into the water system. Two of the other wells and suction mains were rusty and leaked and had not been properly looked after for a number of years. Then came a sudden sharp epidemic of diarrhea, June 26. Probably 2,000 persons were affected. It soon developed that the prevailing disease was typhoid fever. The epidemic began June 26 and gradually died out by Nov. 20, 1908. From July 7 to Nov. 20, 464 cases of typhoid fever were reported to the Health Officer. Of these cases, 401 were considered primary and 57 secondary or contact cases and six outside or imported infection.

This water-borne outbreak of typhoid fever is particularly instructive from the fact that Delia McKeever and Kate Flanagan, administratrices of the estates of their husbands, who died of the fever, sued the city of Mankato for damages. The city demurred to this complaint on the grounds that as a government it was exempt because it was carrying out a government function. The Supreme Court of Minnesota held that "the state is liable if negligence can be proved." The decision of the

Supreme Court in holding the city liable sets an excellent precedent which places the responsibility where it should be. Citizens are evidently as much entitled to reasonable sanitary protection as they are to police protection, or to protection from accidents at grade crossings. It is a fortunate day for preventive medicine when the principle is recognized that sanitary negligence is just as culpable as the negligence which fails to place a red flag or a red lantern to warn against a pitfall in the public highway.

Fig. 3-7. Typhoid epidemic at Ashland, Wisconsin.

**The Typhoid Epidemics of Lawrence and Lowell.** During the years 1890-1891 a typhoid fever epidemic occurred in Lowell and Lawrence, Massachusetts. This epidemic illustrates with great clearness what occurs when streams are used both as sources of water supply and as receptacles for sewage. Both cities are on the Merrimac River, which was grossly polluted by the sewage of Manchester (population 44,126), Haverhill (population 27,412), Nashua (population 19,311), Concord (population 17,004), Fitchburg (population 22,037), Newburyport (population 13,947), Marlborough (population 13,805), Clinton (population 10,424), and from other sources of pollution. In Lowell, 550 cases of typhoid fever occurred from September, 1890, to January, 1891. The epidemic was carefully studied by William T. Sedgwick, who made a most thorough investigation.

A short time after the epidemic in Lowell typhoid fever broke out in Lawrence, nine miles downstream, and rapidly increased. The relation between these two epidemics was most striking. Lowell discharged its sewage into the river, Lawrence drank the water without filtration. The climax of the Lawrence epidemic occurred about one month after that in Lowell. In 1892, there was a repetition of this episode.

Typhoid fever in Lowell was again responsible for an increase of typhoid fever in Lawrence. As a consequence of these occurrences, Lowell abandoned the river and introduced a ground water supply, while at Lawrence a filtration plant was constructed which has materially reduced the amount of typhoid fever in that city (Whipple).

**The Typhoid Epidemics of Pittsburgh and Allegheny.** These two Pennsylvania cities are situated at the junction of the Allegheny and Monongahela Rivers, where they unite to form the Ohio. In 1900, Pittsburgh had a population of 321,616 and Allegheny 129,896. Pittsburgh took its water from the Allegheny River at Brilliant Station, six miles above the junction of the rivers, and from the Monongahela River at a point three miles above the junction. Allegheny received its water supply from the Allegheny River at Montrose, 10 miles from the junction; it was drawn from a rock-filled crib, and was practically unfiltered water. Both the Monongahela and the Allegheny Rivers are grossly polluted streams, receiving the sewage from a populous watershed; in addition the sewers of the cities of Allegheny and Pittsburgh empty directly into these streams, and on account of the rapid growth of these cities much of this sewage entered the river dangerously near to the water intakes. The records of the Board of Health show that at this time there occurred annually upward of 5,000 cases of typhoid fever.

For about 10 years centering around 1900, Pittsburgh and Allegheny had the unenviable distinction of having the highest typhoid death rate of any city in this country and probably of any large city in the world. At times the rates ran above 150 per 100,000. The conditions were improved by the introduction of slow sand filtration for the city of Pittsburgh. Allegheny, which is now officially known as North Pittsburgh, was furnished in 1912 with filtered water.

**The Typhoid Epidemic at Chicago.** The Chicago epidemic is an illustration of a city using a lake water which is infected with its own sewage. The water in 1892 was taken from Lake Michigan opposite the city at several "cribs" which were one and one-half to four miles off-shore. The Chicago sewage was discharged all along the water-front, while the Chicago River penetrated the city with its north and south branches and, polluted almost beyond endurance, flowed out into the lake about midway between the upper and lower cribs. The pollution of the lake water was at times so intense that the foul river water could be traced to the intakes with the eye. This intolerable situation resulted in the building of the Chicago drainage canal, the object of which was to keep the sewage out of the lake and carry it down the Des Plaines and Illinois Rivers into the Mississippi. By the construction of this canal the flow of the Chicago River was reversed so that, instead of the sewage entering the lake and polluting the water supply, the water of Lake Michigan now flows into the Chicago River and thence, through the drainage canal, into the tributaries of the Mississippi. In other words, the sewage of Chicago, instead of entering Lake Michigan, drains to the Gulf of Mexico. During the years 1890, 1891 and 1892 typhoid fever was unusually prevalent in Chicago. In 1890, 1,008 of the inhabitants died from typhoid fever, in 1891 the death toll from this preventable disease was 997 and in 1892, 1,489. Conditions in Chicago, owing to the improvements in the water supply, including chlorination, general pasteurization of the milk supply, and an attack upon the residual typhoid as contact infection, had reduced the death rate to 0.4 per 100,000 in 1932.

The above water-borne typhoid fever epidemics have been selected as examples. Many more may be found in the literature. Whipple, in his book, *Typhoid Fever*, cites numerous instances and gives in tabular form an impressive list of such outbreaks, with reference to the literature.

The water-borne outbreaks of typhoid fever, diarrhea and dysentery which occurred in the United States and Canada from 1920 to 1930 have been analyzed by Wolman and Gorman (1931) and from 1930 to 1936 by the Committee on Water Supply of the American Public Health Association (1938). The following table is quoted from the latter source. In the United States, the largest number of

Table 3-6. Water-borne outbreaks in the United States, 1930-1936, classified as to point of pollution in water system

Point of Pollution	Outbreaks	Cases Typhoid Fever	Cases Diarrhea and Dysentery	Total Persons Affected
A. Untreated surface water	34	442	3,283	3,725
B. Untreated ground water	64	1,378	1,780	3,188
C. Contamination reservoirs and cisterns	4	17	196	213
D. Inadequate control over water purification	15	608	9,678	10,286
F. Contamination in distribution system	15	287	1,975	2,266
G. Contamination in collection or conduit system	2	5	0	5
H. Miscellaneous	36	443	1,969	2,412
TOTAL	170	3,180	18,881	22,095

Adapted from Rep. Comm. on Water Supply, Am. P.H. Ass'n, Year Book, Am. Pub. Health Ass'n, 28: Table VIII, 1938.

outbreaks of cases of typhoid fever was due to the use of untreated ground water supplies, this being the cause of 64 out of 170 outbreaks. Next in importance were untreated surface waters, rivers, small streams, ponds and lakes, which account for 34 out of 170 outbreaks. It is highly significant from a public health standpoint and important to note that errors in treatment of water and subsequent delivery of this water to the consumer caused 30 outbreaks. Bathing in polluted water is thought to have caused only three of the 170 outbreaks. The evidence on which this latter conclusion is based is not given in detail.

**Other Modes of Transmission.** ICE. Ice may, under exceptional circumstances, occasionally be the vehicle by which typhoid bacilli are transferred. Freezing does not kill *B. typhosus*, but there is a great quantitative reduction not only in the act of freezing but also during storage; hence the danger is greatly lessened. The only suggestive outbreak of typhoid fever attributed to ice was reported by Hutchins and Wheeler in 1903 in the St. Lawrence Hospital three miles below Ogdensburg. A few other instances in which ice is believed to have conveyed the infection have been reported, but are based upon flimsy evidence. The fact that natural ice is usually stored many weeks or months before it is used is a sanitary safeguard. Manufactured

ice made from distilled water and handled with cleanly methods is above reproach.

**MILK.** Milk usually becomes contaminated on the farm from a case or a carrier. It may also become contaminated in transportation, at the city dairy, or in the home. Milk-borne outbreaks are practically always due to raw milk; there is no case on record of such trouble coming from properly pasteurized milk. On account of the almost universal custom of boiling milk in European and tropical countries, milk outbreaks are rarely found in these regions.

In the United States, raw milk has been a frequent vehicle of distribution of typhoid infection in the past (see Table 22-2, page 868). While the potential danger is still present, milk-borne epidemics have become increasingly rare in recent years as the sanitary quality of milk supplies has been improved and pasteurization has become almost universal.

**MILK PRODUCTS.** Fresh milk products, such as cream, ice cream, butter and buttermilk, and fresh cheese, may contain the typhoid bacillus, and, if they are not subjected to a pasteurization process, are occasionally media of communication.

*Cream* contains more bacteria than the milk from which it is taken. The use of infected cream in coffee, on cereals, etc., is sufficient to cause the disease. As a rule, coffee in the cup is not hot enough to kill the typhoid bacillus, if present in the cream added.

Mitchell working in Rosenau's laboratory found that *S. typhosa* survives in ice cream for from 12 to 39 days. Lumsden (1917) traced the Birmingham, Alabama, outbreak in 1916, and another in Chattanooga, Tennessee, to ice cream. An outbreak at Helm, California, was found by Cumming (1917) to be due to ice cream.

Bruck has shown that the typhoid bacillus will live in butter for 27 days.

The acidity and overgrowth of other organisms in *buttermilk* is said to inhibit growth of the typhoid bacillus in 24 hours. In *cheese* the time of fermentation, antibiosis, aging, etc., lessens the likelihood of survival of the typhoid bacillus. Fresh cream cheese, such as cottage cheese, may be responsible for an occasional case.

**OYSTERS, MUSSELS AND SHELLFISH.** The first outbreak of typhoid fever established as due to this source was investigated by Conn at Wesleyan University, Middletown, October, 1894. Twenty-five cases were attributed to eating infected oysters; four died. Not all of those who took sick had clinical typhoid fever. Some had gastro-intestinal disturbances with illness lasting but a few days. About one quarter of those attending the dinners at which the oysters were served were made ill.

L. W. Darra Mair (1909) showed that much of the typhoid fever in Belfast, Ireland, from 1897 to 1901, was due to eating cockles and mussels taken from sewage polluted water. The amount of the fever diminished markedly and its seasonal prevalence was changed by betterment of the shellfish situation.

In Brighton, England, J. T. C. Nash (1909) proved that much of the typhoid fever in the Borough of Southhead-on-Sea prior to 1899 was due to infected oysters. There was a sharp reduction in the amount of fever when the foreshore fisheries were stopped, and almost a cessation of all cases when attention was given to all shellfish, including the improved laying and cooking of cockles. The largest outbreak due to oysters occurred in the United States in 1924. Oysters become dangerous when consumed soon after taking them from a polluted bed, or when floated or bloated in infected water. For further discussion of this topic, see page 908.

**FRUITS AND VEGETABLES.** Vegetables, such as celery, lettuce, watercress and radishes, partaken raw, and grown on land fertilized with fresh night soil, may be infected, and this probably accounts for an occasional case. Vegetables so contaminated are not made safe by the ordinary methods used in preparation of such food for table use. In large cities it is practically impossible to trace this source of infection. It therefore remains more a suspicion than a conviction.

**FLIES.** The common house fly (*Musca domestica*) may convey the infection of typhoid. The typhoid bacilli may be smeared upon the feet or other parts of the insect, or may live in the intestinal tract and pass in the dejecta in almost pure culture. Some species of flies live, feed and breed in fecal matter and decomposing organic substances of all kinds. It is easy to see how they may convey infections from this source to our food, lips or fingers. Alice Hamilton isolated typhoid bacilli from 5 out of 18 house flies captured in Chicago in the privy and on a fence near a sick room during a local water-borne epidemic. It has been shown experimentally that living typhoid bacilli may remain upon the bodies of flies for as long as 23 days. Special attention to the role played by the fly was given by Reed, Vaughan and Shakespeare in their studies of the prevalence of typhoid fever in our army camps in 1898. They concluded that flies undoubtedly served as carriers of the infection and attributed about 15 per cent of the cases to this mode of communication. They found that "flies swarm over infected fecal matter in the pits and then deposit it and feed upon the food prepared for the soldiers at the mess tents. In some instances, where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with lime were seen walking over the food." The danger from fly transmission varies very much, and depends upon circumstances. In a camp it is considerable; in a well sewered city the risk is diminished. In the Washington studies no relation was found between fly abundance in the summer of 1908 and typhoid prevalence. The danger of typhoid from flies in cities has doubtless been overstated. However, if infection were transmitted only occasionally, the suppression of flies would still be quite worth while.

**DUST.** Typhoid bacilli soon die when dried, especially when exposed to the sun and air. Dust-borne infection in this disease must be rare.

**FOMITES.** The infection may be conveyed upon soiled linen, blankets and other objects. It was believed by Reed, Vaughan and Shakespeare that the clothing, blankets and tents in the Spanish-American War became infected and were a prime factor in spreading the disease. The danger of fomites contaminated with fresh infection is real, and emphasizes the importance of disinfecting bedding, towels, handkerchiefs, body linen and other fabrics.

**SOIL.** From a study of the longevity of *S. typhosa* in various kinds of soil, Beard (1940) concluded that the most important apparent factor determining survival was moisture. Fifty per cent of typhoid bacilli will probably die during the first 48 hours. Survival of the remainder may extend over a period of months, depending upon conditions.

**CONTACT.** "Contact" is a convenient term to indicate the spread of infection directly or indirectly as a result of close association between the sick and the sound. Actual contact is not necessarily implied. The term is used to indicate the transfer of the infection through a short intervening space in a brief period of time. Thus, the infection may be passed from one to another through soiled hands, remnants of

food, infected thermometers or tongue depressors, contaminated towels or other fabrics; cups, spoons, glasses, etc. The infection may also be spread in the household by flies, fingers, and various other means, usually difficult to trace, and which are, therefore, all included under this general designation. Regarded in this light, contact plays a large role in the spread of the disease.

Extensive municipal outbreaks have been reported as largely or entirely due to contact transmission. Winslow, in 1901, studied such an outbreak in Newport. Others have been reported from Knoxville, Winnipeg, Springfield, and from Germany and England. Koch regarded the spread of typhoid in Trier in the light of contact infection. Freeman thought that the majority of outbreaks in the smaller towns of Virginia were due to this cause. Extensive outbreaks in institutions are often due to contact with missed cases or carriers. "Flies, fingers, and food" (Sedgwick), and "dirt, diarrhea, and dinner" (Chapin), which too often get sadly confused, explain the occurrence of many a case of contact infection.

#### TYPHOID VACCINES

**Preventive Typhoid Inoculations.** Our knowledge of inoculations against typhoid fever began with the work of Pfeiffer and Kolle, who inoculated two volunteers in 1896. About the same time, Almroth Wright inoculated several persons, and in 1898 continued the work upon an extensive scale in India upon 4,000 British soldiers. In 1900, during the Boer War, Wright, together with Leishman, prepared a vaccine and supervised the inoculation of 100,000 British troops. The results in India were quite encouraging, but for various reasons the same procedure in South Africa was not as satisfactory as had been anticipated. Prophylactic inoculation on the advice of Koch was used by the Germans in the Herero campaign in southern West Africa in 1904. The prophylactic was voluntary and only about half of the command (7,287 men) availed themselves of it. The results, while good, fell short of expectations.

In the United States, production of typhoid vaccine for use in the Army was initiated by Brig. Gen. Frederick Russell in 1908. The original procedure adopted was a modification of the English and German methods, the aim being to make a sterile standard suspension of typhoid bacilli with their essential immunogenic constituents as little changed as practical. Typhoid inoculations were recommended as a voluntary protection in 1909 and were made compulsory in 1911, and have been required by Army regulations since that time. Subsequently, the development and improvement of methods of production and administration of typhoid vaccine for use in the United States has resulted very largely from studies conducted in the research laboratories of the Army Medical School. The objective has been to develop a vaccine which would afford a maximum degree of protection with a minimum frequency of unpleasant reactions from its administration. In other words, a balance was sought between high immunogenic potency and low toxicity. The history of the changes and the results obtained in the prevention of typhoid fever by the use of vaccines produced as modified from time to time has been reviewed by Siler and his associates (1941).

The principal modifications introduced have been related to the selection of strains for inclusion, the numbers of organisms per ml. of vaccine, the technic of inactivation by heat and chemicals and the dosage injected. Originally, the Rawlings

strain of *S. typhosa* was used in preparation of the vaccine. As a result of studies of strains suitable for the production of vaccines of optimum antigenic composition, with particular reference to the Vi antigen, in 1936 a new strain (#58) of *S. typhosa* was substituted. Originally, a monovalent typhoid vaccine was produced. During World War I, because of the possibilities of exposure under field conditions, strains of *S. paratyphi* A and *S. paratyphi* B were included in the vaccine, so-called triple vaccine or T.A.B. Since that time, practice has varied with regard to the inclusion or exclusion of paratyphoid organisms. The Army regulations now in force require the use of triple vaccine.

In the standard procedure, typhoid bacilli are cultivated on veal infusion agar, harvested after 18 to 24 hours of incubation at 37° C by emulsification with normal saline, killed in a water bath at 56° C. The suspensions are then standardized as to bacterial content. The method used for this estimation is much more accurate than it was formerly. The content of the triple vaccine now in use (Longfellow and Luippold, 1943) is as follows: 1,000 million *S. typhosa*, 250 million *S. paratyphi* A, and 250 million *S. paratyphi* B per ml. of vaccine. The pH of the preparation is adjusted to approximately 7.2, tricresol 0.25 per cent is added as a preservative.

Since infections with *S. paratyphi* A and B are extremely rare in the United States, the monovalent *S. typhosa* vaccine is advised for the civilian population.

Initial vaccination consists of a subcutaneous injection of three 0.5 ml. doses of vaccine administered at intervals of seven to 28 days. Reactions from this dosage are usually moderate. There is always some local tenderness at the point of inoculation, with a variable amount of swelling, edema and pain. When the injection is made in the upper arm, the axillary lymph glands usually become large and painful. In a small proportion of individuals a systemic reaction, varying in severity, follows within a few hours and is manifested by headache, chills, fever, lassitude, muscular pains, malaise, nausea and urticaria. An indication of the frequency of local and systemic manifestations is afforded by Table 3-7 based on Luippold's (1944) observations on 115 medical students who had received T.A.B. vaccine. The systemic symptoms usually subside in 24 hours.

Concerning the protection conferred by an initial course of three injections of typhoid vaccine, it can be said that it develops gradually, reaching its maximum a week or two after the third injection and then gradually decreases. How long it lasts is uncertain. Laboratory procedures, such as the titration of agglutinins in the blood serum and mouse protection tests, afford an indication of immunity (Luippold and others, 1947) but have not been correlated in an exact manner with protection from attack in a human being naturally exposed. There are many factors involved in immunity to typhoid infection which are not understood.

The evidence available indicates that to maintain a maximum degree of protection against typhoid it is advisable to revaccinate or inject a stimulating dose every two or three years. In the United States Army, revaccination by stimulating doses is required annually. For this purpose, a subcutaneous injection of 0.5 ml. of vaccine or an intracutaneous injection of 0.1 ml. of vaccine is given.

The degree of protection afforded by typhoid vaccination is still a matter of some discussion (Edsall, 1949). The question must be answered by human experience under natural conditions of exposure. Much of the evidence has been derived from observations on the association of its use in a military organization, with the sudden

Table 3-7. Summary of local and systemic reactions following subcutaneous injections of the standard dosage (0.5, 1.0, and 1.0 ml.) of T.A.B. commercial vaccine to 115 persons

Dose of Vaccine	Local					Systemic								
	Average Area of Hyperemia in Sq. Cm.	Degree of Tenderness				None	Head-ache	Chills	Fever	Lassi-tude	Muscu-lar Pains	Malaise	Nausea	Urti-caria
		None	Slight	Mod-erate	Severe									
1st	51	0	35	51	29	67	22	6	11	17	8	10	1	0
2nd	65	0	30	46	39	67	15	4	12	16	12	15	1	1
3rd	45	5	76	24	10	99	7	2	3	5	4	4	0	0

Adapted from Luippold, G. F., Am. J. Pub. Health, 34:1151, Table 12, 1944.

and abrupt fall in the typhoid rate, or with the low rate in comparison with other population groups not so protected. In such comparisons one cannot be sure that the exposure to infection is equal or that other factors may not be responsible for the differences. There have been a few observations on civilian groups in which one could be reasonably sure that the immunized and nonimmunized groups were equally exposed (Murphy and others, 1944; Duncan and others, 1946).

Furthermore, in evaluating this evidence, two elementary principles must be borne in mind. The findings of a particular study do not apply to typhoid vaccine in general but to the specific product and method of administration and circumstances of exposure which obtained with reference to time since vaccination. The second is the fact that no immunizing agent can ever be expected to give 100 per cent protection at all times. Its efficacy is relative to the size of the infective dose and the virulence of the particular strain of the micro-organisms to which the group is exposed. There will always be an infective dose or an interval since inoculation which will overcome whatever protection was induced by vaccination procedure employed. The occurrence of cases of typhoid fever among persons who have been inoculated means only that the vaccine does not always protect. This has been known for no less than 35 years. On the other hand, there is a considerable amount of evidence, direct and indirect, which supports the concept that vaccination against typhoid with the optimum methods of preparation and administration now known, affords a considerable degree of protection for an indefinite time, provided it is maintained by stimulating doses.

Preventive typhoid inoculations involve no risk, and are especially applicable to those unduly exposed to the infection, such as nurses, hospital attendants, physicians, travelers, soldiers in camps, and individuals in the family of a case or carrier.

Typhoid vaccination should be mandatory in asylums and other custodial institutions. The method is serviceable for general use among the public in endemic foci, but it is a question whether this artificial method of acquiring immunity would serve as good a purpose in the end as fighting the disease along the lines of general sanitation, which has been so successfully done in many countries. It would certainly be a mistake to immunize the population with this artificial method to the neglect of general sanitary improvements, such as good water, safe milk, fly suppression, cleanliness and personal hygiene. Because a person has received the protection afforded by typhoid inoculations is no reason for reckless disregard of other prophylactic measures. *Typhoid inoculation is not a substitute for sanitary precautions.*

**Management of a Case so as to Prevent Spread.** Success depends upon an early and accurate diagnosis. All cases of typhoid fever and all cases suspected of being typhoid fever should be isolated. This does not mean imprisonment in a lazaretto. *The proper place to care for typhoid fever is in a suitable hospital.* A private home is a poor makeshift for a hospital, and it is unreasonable to turn a household into a hospital for four to eight weeks or longer. Where this becomes necessary, the room in which the patient is treated should be well ventilated, and should contain no unnecessary furniture, curtains, carpets, etc. It should be near the bath and must be well screened and kept scrupulously clean, dry sweeping and dusting prohibited. Exposed surfaces should be wiped off daily with a disinfecting solution. Dogs, cats and pets of all kinds should be kept out of the sick room.

The case should be reported to the health authorities without delay. Visiting

should be prohibited and no one allowed in the sick room except those who have duty there. The patient should be nursed by one skilled in the technic of preventing the spread of infection.

The health officer should send an epidemiologist or a public health nurse without delay to the premises to instruct and to see that all necessary measures are being taken. The origin of the infection should be studied so as to prevent further spread from that source.

The disposal of the stools, urine, sputum, and other discharges is of the first importance. The methods used will vary with circumstances. Differences in the facilities available will determine what procedures are safe and advisable for the community involved. Disposal of untreated urine and feces by water-carried sewage is a safe procedure in some areas, if legally permissible. Where this does not seem to be advisable, some form of chemical disinfection must precede disposal. For the urine, sufficient bichloride may be added to make a 1:1,000 solution, or carbolic, 2.5 per cent, or formaldehyde solution, 10 per cent, and allowed to stand one hour before discarding. Stools may be disinfected with bleaching powder, 3 per cent; milk of lime (1:8); cresol, 1 per cent; carbolic acid, 5 per cent; formaldehyde solution, 10 per cent; or unslaked lime and hot water. The discharges should be received in a glass or earthenware vessel containing some of the germicidal solution. Then add more of the solution so that it shall be present in twice the volume of the excreta to be disinfected; disintegrate the masses thoroughly and let stand at least two hours, protected from flies. Masses are so difficult to penetrate that they must be broken up thoroughly with a wooden paddle. It takes a strong carbolic solution 12 hours to penetrate the interior of a small fecal mass; larger masses are impenetrable to most germicides. Urinals, bed pans, etc., should be scalded or washed in a disinfecting solution, and when not in use should contain this solution. The sputum should be burned.

The patient should have his own dishes, cups, spoons, glasses, etc., which should be kept and washed apart; they should be scalded after each use. Remnants of lunch, especially meat, milk, gelatin, broths, and other organic food in which the infection may live and even grow, should not be eaten by others. Such remnants may be burned or first boiled and then discarded. Those who nurse the sick should keep out of the kitchen on account of the risk of contaminating the food.

Handkerchiefs, towels, sheets, nightgowns and all fabrics used about the patient should be disinfected by boiling.

Milk bottles must be kept out of the sick room. In any case, they should be scalded before leaving the house and again disinfected before returning to the dairy.

The thermometer should be kept in formaldehyde solution, alcohol or other suitable germicidal solution. Rectal tubes, especially in hospital practice, must be carefully disinfected each time before using. Individual instruments are preferable. For children inexpensive toys and books may be provided during convalescence and then destroyed.

The nurse must protect herself as well as others. Every time the patient is bathed, his mouth cleaned, or his buttocks washed, the hands must be washed in soap and water and disinfected. The nurse must exercise especial care if she is to go to the kitchen or to the ice box, etc., as is frequently the case in private houses, where a special diet kitchen cannot be provided.

The nurses, physicians, ward attendants, familial associates, and others particularly exposed should be protected by preventive typhoid inoculations. The physician should be quite as careful as the nurse, not only that he may not carry the infection to himself or other patients, but also that his practice may serve as a stimulating example.

At the conclusion of the case a general cleansing and disinfection of the room and its contents should be practiced, followed by sunning and airing.

Convalescents should not be given liberty until the danger of bacillus carrying has passed. This may be determined only by bacteriologic examinations of the stools and urine. Three successive negative cultures of feces and urine specimens, collected not less than 24 hours apart and not earlier than 7 to 10 days after the patient becomes afebrile are required to determine that the carrier state is not established.

**Summary.** The decrease and gradual disappearance of typhoid fever from the United States and other advanced countries is an outstanding example of control by preventive medicine and environmental sanitation. The steps to this achievement are well known. The first requirement is to eliminate dissemination through public water supplies to urban populations. In the United States improvement began in the 80's and 90's and took place in one city after another as practical methods of purification of water developed. Particularly important in this connection was the introduction of chlorination about 1908 and gradual enforcement of standards of water safety based upon adequate engineering consideration of sources of supply, improved methods of treatment and purification, safeguarding the distribution system, and the use of frequent chemical and bacteriological analyses. These measures were gradually extended from the cities to the smaller towns and villages through the activities of sanitary engineering divisions of the state health departments. Along with the improvement in water supplies came the extension of water-borne sewage systems. Common practice during the latter part of the nineteenth century was to discharge raw sewage into streams and ponds and lakes. In the heavily polluted areas surface streams, ponds and lakes become open sewers. Gradually, this situation has been ameliorated by the installation of sewage treatment works; much still remains to be done. Second only to water as a vehicle of wide dissemination were the common milk supplies. At the turn of the century these were practically without sanitary regulation; a low standard of cleanliness prevailed with regard to milk distribution; the product was delivered to customers in the raw state. Gradually, during the past half century adequate standards of cleanliness have been set up and enforced, production and distribution have been brought under sanitary supervision and more than 95 per cent of the supplies in this country are pasteurized before delivery to the customer. Similar improvements have been effected in protecting milk products. With the elimination of milk-borne and water-borne typhoid in the cities, prevalence rates declined rapidly leaving so-called residual typhoid in the areas adjacent to the cities and in the rural districts. To provide safe water and proper sewage disposal for private homes was a slower process but has gone on continuously. Decrease in the fly nuisance as the horse was superseded by the motor driven vehicle undoubtedly played a role. There was an increasing use of hospitals for the isolation of clinical cases of typhoid fever with consequent reduction in frequency of contact infections. The opportunities for dissemination of fecal material from person to person was reduced gradually by the improvement of home hygiene through education of the

public and better economic conditions. Toward the latter part of the period under consideration, the use of prophylactic vaccine undoubtedly became a factor but its application was limited geographically and to especially exposed groups.

The problem in this country has now become one of small towns and rural districts, of sporadic cases and focal outbreaks. Control has become increasingly a matter of prompt diagnosis and isolation of patients for the protection of contacts, and the tracing of sources of infection. The discovery and supervision of carriers has become an important health department function.

The ultimate reservoir of infection with typhoid is the number of carriers in the population. Their numbers are being decreased through deaths more rapidly than they are being replaced by new carriers arising from cases. The balance is against the survival of the disease and ultimately elimination from large areas is to be anticipated.

## SALMONELLOSIS

JAMES WATT, M.D., DR.P.H.

Salmonellosis is a convenient etiologic term to describe a variety of conditions of man and many animal species. The causative agents are Gram-negative, lactose-negative rods, grouped together on biochemical and serological grounds into the genus *Salmonella*. Most of them are fairly common parasites in the tissues of sick animals and birds, but they abound particularly in the intestinal tracts of these hosts, both healthy and diseased. Salmonellosis may, on occasion, result from the ingestion of food containing the organisms; but since this is only one of numerous modes of spread, such qualifying terms as "food infection" seem undesirably restrictive in a general context.

In humans, the clinical picture of salmonellosis ranges from severe enteric fever, septicemia, dysenteric syndromes and such focal manifestations as pneumonia, meningitis and arthritis, to gastroenteritis, trivial diarrheas, and the healthy carrier state. Clinically and epidemiologically, there are good reasons to consider typhoid fever (*Salmonella typhosa*) separately, but the reasons for a blanket segregation of the so-called paratyphoid fevers are less cogent, and in the following discussion, diseases caused by *Salmonella paratyphi A*, *S. paratyphi B* or *S. paratyphi C* will be singled out from other salmonellosis in certain particulars, and lumped with them in others, as the facts require.

## SOURCES AND SPREAD

There are five main threads in the development of our knowledge on this subject. The first *Salmonellae* to be identified came from material in an outbreak resulting from the consumption of the flesh of a fatally infected animal. For over 50 years since, the bulk of the literature on salmonellosis has been oriented with reference to the problem of "food poisoning." In fact, salmonellosis has until recently been considered practically synonymous with "food poisoning." A second element entered the picture as more was learned about the role of the *healthy carrier* in typhoid

fever. Much effort has been spent attempting to evaluate the same factor in other *Salmonella* infections. Third, much has been made of the part played by such *vectors* as rodents, flies, roaches, and lately even ticks and fleas. Fourth, recent work has suggested that *household pets* may serve as a significant source of salmonellosis. Finally, while in most salmonelloses the secondary attack rate is not very high, nevertheless the *sick individual* himself may be a danger to others, particularly (as is also the case with carriers) in such environments as food handling establishments, mental hospitals and pediatric wards. Infants have acquired *Salmonellae* at birth, as a result of an infection in the mother.

It must be emphasized that the all important common denominator among the sources listed above is *human or animal feces*. With rare and not always well documented exceptions, such as naso-pharyngeal exudate and the flesh of animals following tissue invasion, *contamination of food by feces* or any other mechanism which results in the *ingestion of fecally contaminated material* is the gist of the matter. *Salmonellae* are primarily enteric pathogens, and if one bears this simple epidemiological principle in mind, the complexities of the sources and spread of salmonellosis tend to disappear.

**Food.** Prepared food containing *Salmonellae* represents a very late link in the chain of transmission. It may contain the organisms because it has been contaminated at any stage in its preparation or processing, or it may contain them because the animal from which it came was infected with *Salmonellae*, whether symptomatic or not. Examples of the first type are contamination by sick or healthy humans harboring *Salmonellae*; by sick or healthy vectors; or from utensils or other food. One example of the second type is the egg which contains *Salmonellae* from the tissues or feces of the hen. Another example is the epidemic of acute diarrhea following the consumption of meat from a sick animal. Today, however, since in many parts of the world, flesh from obviously sick animals is infrequently consumed, and since the consensus is that heavy invasion of the tissues seldom, if ever, occurs in the absence of obvious clinical disease, a much more important problem concerns healthy animal intestinal carriers. The problem assumes major proportions when food is processed in bulk or by assembly line technics, and contamination of the meat of many carcasses occurs from the gut contents of a single carrier animal. This distinction between antemortem infection and postmortem contamination is often highly important in epidemiological studies, particularly with regard to control.

Thus, meat is a major source of salmonellosis. Pork and poultry are the most frequent culprits, and both have been definitely convicted in countless outbreaks. Both swine and fowl suffer from symptomatic salmonellosis and both species are capable of assuming the carrier state. Historically, pork was one of the earliest to be accused, and as recently as 1936 a law suit was decided against an eating establishment on the basis that pork was included in the meal, whereas, no importance was attached to the fact that the victim's previous meal included roast fowl, which, in the light of our present knowledge, is at least as likely to have been the vehicle of infection.

**POULTRY.** Information on the prevalence of infection with *Salmonellae* in domestic animals is meager, since the majority of studies have been concerned with sick animals only. The few studies which have been made on domestic animals in the normal population indicate that practically all animal species are positive. The fre-

quency distribution of the various sero-types correspond in general rather closely with the types found in man. To illustrate: 1.3 per cent of normal chickens in Mexico had *Salmonellae* in the intestinal contents. A sample of normal chickens in Texas showed 0.75 per cent positive for *Salmonellae* in their feces. The studies on turkeys indicate that these birds are possibly more likely to carry the *Salmonella* organisms than are chickens. A number of outbreaks of human disease have been attributed to roast turkeys. A special factor may be the larger size of this bird which makes it more difficult to cook thoroughly. The importance of contamination of meat during processing is illustrated by a culture study showing that a single infected turkey carcass contaminated many other carcasses during dressing. This contamination was found to largely disappear in a few days, but not if the carcasses are frozen. Ducks commonly have salmonellosis and numerous epidemics have been traced to these birds.

**Hogs.** There is evidence that perhaps 10 to 15 per cent of normal hogs are healthy carriers. Many independent studies of the mesenteric lymph nodes of hogs on the slaughter house floor have yielded closely similar results, ranging from 5 to 20 per cent. Rates up to 70 per cent of individual lymph node involvement have been observed in sick hogs discarded at the slaughter house. Here is other evidence of contamination during processing: in one abattoir in which 20 per cent of the lymph nodes were positive when collected aseptically, the rate was 60 per cent when ordinary slaughter house methods were employed.

**EGGS.** Duck eggs as a source of outbreaks of salmonellosis are only too well known, especially in Europe. The suggestion is sometimes made that the relatively unhygienic habits \* of ducks compared with those of chickens may have something to do with the particular importance of duck eggs as compared to hen's eggs.

Recently, however, hen's eggs have been incriminated with exceptionally strong evidence in various outbreaks. Culture studies on market eggs have been a source of information. It is also known that experimentally infected chicks (the survivors) will carry *Salmonella* for a long period, that 4 to 10 per cent of the eggs of the survivors will be positive in either shell or meat, that known positive flocks produce up to 30 per cent positive shells and 1 per cent or more positive meats. Opinion, it should be noted, is divided as to the relative importance of shell vs. egg meat, though the consensus points to the shell as definitely the more important. The shell, the yolk and the white of the egg may all contain *Salmonellae*. The organisms have been shown to survive up to three weeks at room temperature, and as long as 30 days in duck eggs. Dirty-shell eggs are about four times more frequently positive than clean eggs, and about twice as frequently positive as washed dirty eggs. This, of course, is in agreement with the known fact that healthy chickens are frequently fecal carriers. In one survey, 0.6 per cent of storage shells were positive. Washing the eggs, especially in cool or cold water or immediately after laying, increases the likelihood of shell penetration, as indeed do any conditions of increased environmental moisture. Penetration is greater in the incubator than at room temperature. Clean eggs almost always have sterile meats; washed dirty eggs often do not, though they may be marketed as "cleans." Around 5 per cent of dirty eggs may have positive meats and around 15 per cent of dirty eggs may have positive

\* They "practice their amours and lay their eggs in any old ditch." (Lecoq.)

shells.\* Eighty per cent of experimentally positive eggs hatched into positive chicks, none of which however showed signs of disease and many of which continued to carry the organisms. From the poultryman's point of view the major problem centers around the incubator with its environment of increased moisture and temperature in which *Salmonellae* have been shown experimentally to survive as long as 111 days.

Powdered egg is undoubtedly a more serious matter than the fresh egg. A consistent figure of around 30 per cent positive for *Salmonellae* other than pullorum is the rule for samples from commercial powdered egg factories. The number of organisms, however, is quite low and apparently no multiplication occurs in the dry powder. It follows, therefore, first that egg powder with low moisture content is safer than egg powder with high moisture content, and secondly, that significant danger arises when reconstituted egg mixture is permitted to stand at more than 15° C, where the organisms can multiply. The relative importance of shell vs. meat in the egg powder problem is unsettled but opinion is leaning towards shell. It is proven that the multiplication of bacteria does take place during the processing of eggs, especially when unnecessary lags occur or "pockets" of mixture collect. Organisms disappear fairly rapidly from egg powder on storage, but less rapidly when the powder is stored cold.

**OTHER FOODS.** The problem in other foods is mainly one of contamination. In the past many outbreaks have been attributed to milk and cream products, including synthetic cream. The evidence incriminating milk is not very good and many of the outbreaks were reported before any importance was being attached to the use of eggs in the same milk products. The evidence for the secretion of *Salmonellae* in cow's milk is equivocal. *Salmonellae* have occasionally been found in the udder, but there is no instance of milk collected under sterile conditions being positive on culture. Moreover, cows are well-known fecal carriers, and contamination from that source is probably the rule in the rather rare instances where milk is incriminated.

*Salmonellae* have been shown experimentally to survive for weeks or months in canned fruit, butter, cheese, brine, cereals, bread and they can live for many days on kitchen utensils. They will multiply in milk at 15° C and they will survive at freezing temperatures. Fish smoked or pickled in the ordinary way may contain infective amounts of *Salmonellae*. Dilution of some food seems to favor survival.

For many years, in the face of an outbreak of salmonellosis, epidemiologic investigation focused on the food immediately before consumption, that is, on the last link in the chain of transmission. Excluding the rare case in which a sick animal was slaughtered for food purposes, it was usually assumed that either a human carrier was involved or an animal such as a rat or mouse. It is only fairly recently with the increasing realization that the *original animal source is important* and that *healthy animal carriers are fairly common*, that we have begun to look further backward in the chain of transmission, but at this time we do not have the necessary information to compare the relative importance of different food sources and means of spread, beyond the perhaps crude generalization that pork, fowl, duck eggs, and

\* Throughout this section, as above, figures refer to *Salmonellae* other than pullorum. Incidentally the pathogenicity for humans seems to be well established by one or two well studied outbreaks; however, the degree of pathogenicity is extremely low, and outbreaks attributable to pullorum must be correspondingly rare.

powdered eggs appear to stand out far above all other food as immediate sources; and that ultimately the food is most often contaminated by the feces of the animal in question. Food sources thus defined appear at this time to far outweigh contamination by vectors and—except for certain sero-types—to exceed food contamination by carriers.

**Rodents and Arthropods.** *Rats and mice* have been traditionally considered the main culprits in the spread of salmonellosis but data are fragmentary and disconnected. Rats and mice may suffer salmonellosis often and continue to carry the organisms as healthy carriers for months or for life. There are gallbladder carriers among rats. Discovered prevalence rates vary from 1 to 20 per cent, and this variation seems to depend largely on whether the animals are trapped in a packing house or restaurant area or elsewhere where they have access to *Salmonella* contaminated food. Another variable depends on whether fecal studies are made or cultures of the blood and viscera. The latter are consistently higher, but the former are more directly related to the problems of human disease. It is difficult to find a single outbreak convincingly attributed to one of these animals. Too many investigators stop studying a *Salmonella* case as soon as they find a mouse pellet in the house or get a positive culture from an animal. The possibility must always be borne in mind that the animal and the human case may have been collaterally infected from a common source. As of 1950, some commercial rat poisons were still incorporating *S. enteritidis* as the rodenticide. This practice is indefensible since it is not an effective rodenticide and does create a reservoir of rat carriers.

**FLIES.** A significant amount of air-tight evidence against flies is not easy to collect. The experimental case, however, against the fly is proven to the hilt. *Salmonellae* have been isolated from the bodies of flies, from maggots and from fly eggs. It is known that eggs hatched in contaminated mash then washed antiseptically will produce infected adult flies. The house fly can carry *Salmonella enteritidis* throughout its lifetime. *Salmonellae* have been isolated from flies caught in their natural environment. On the other hand, in a study designed to show the effect of fly control on diarrheal disease in Texas, the degree of control attained had little if any effect on *Salmonella* prevalence. This stands in marked contrast to the effect on *Shigella* prevalence since in this group of organisms a significant reduction was demonstrated.

**ROACHES.** Experiments have shown that several species of roaches feed readily on human feces, and that when they are artificially infected with *Salmonellae* about half die and perhaps one-third remain infected for a month or more during which they intermittently excrete the organisms in their feces. Roach pellets may remain positive for 199 days at room temperature. The exterior surfaces of a roach may remain positive from a single contamination for 78 days. Roaches can transmit the disease to other roaches and it is worth recalling that the fecal pellets of some common species are large enough to be mistaken by the naive for mouse droppings.

Wood ticks have been shown to be infectable with *Salmonellae* and capable of transovarian transmission to their offspring. Dog ticks have been more or less convincingly incriminated in epidemics of *Salmonella* enteric fever in kennels. Many other animal species are known to harbor *Salmonella*, including armadillos, snakes, and small birds.

In summary, the case against arthropods and rodents is circumstantial and the

lack of direct evidence in itself indicates that they probably play a minor part in the spread of human salmonellosis.

**Pets and Non-Food Animals.** One of the latest developments in the *Salmonella* field is the increasing interest in dogs and cats as a source. This development is related to the shift in emphasis from epidemic disease, especially food poisoning, to endemic sporadic cases which are believed by many to constitute on the whole a more serious problem. Several outbreaks involving single cases or groups of cases in a household have called attention to the simultaneous or preceding infection of the family dog. The animal is sometimes symptomatic with diarrhea or other disease and sometimes is asymptomatic. In Australia, a large outbreak was related on epidemiologic grounds to a preceding outbreak of typhimurium enteritis in cats. Salmonellosis in cats and dogs may cause abortion, diarrhea or a variety of symptomatic and asymptomatic conditions.

A few surveys are available. Eighteen of 100 dogs in Michigan were excreting *Salmonella* in their feces. Most were subclinical cases or convalescent or healthy carriers. In Texas, over 3 per cent of 1,100 unselected dogs and over 3 per cent of 600 cats had positive fecal cultures. In this same survey, a significant deviation in one town from the sero-type distribution found in all surrounding towns in humans was duplicated in the animal population with very impressive correspondence. There was, in addition, an individual case of a child and a cat with which the child played, both harboring a previously unreported type of *Salmonella* not found in any other person or animal during this survey. One survey of many dog kennels has shown up to 100 per cent fecal excretors. In London, a sample of well dogs showed five positive out of 500, and seven of 500 cats.

Salmonellosis is not widely recognized by veterinarians as an important disease of dogs and cats. There are probably few cases in relation to the number of carriers. There is a fertile field for further investigation in correlating the prevalence rates of disease and positive cultures of small animals on the one hand and veterinarians and kennel keepers on the other hand. This is essentially the same need that is felt in connection with studying the poultry problem, and disease among poultrymen and poultry dressers as compared with control groups from the general population.

**The Sick Patient.** In a general way, it may be said that the sick individual is important as a source in inverse proportion to the severity of his disease. Subclinical cases and mild diarrheas may be extremely important, especially when such persons are employed and continue to work as food handlers, nurses, etc. Occasional outbreaks present epidemiologic features suggesting contact transmission, being less surely or semi-explosive in development. Many small outbreaks in the literature concern a number of severe cases convincingly attributed to an associate with a mild, almost unnoticeable syndrome and later found to have a positive stool culture. Particular attention should be given to this kind of problem where groups of different susceptibility are concerned, as, for example, in the pediatric wards of hospitals. Children are unquestionably more susceptible to salmonellosis than adults, and newborn infants may be infected at the time of delivery. Such an infant may, of course, in turn serve as a source of a serious outbreak in the newborn ward. The nasal secretions of infants and children with salmonellosis are frequently positive and this suggests an additional means of transmission from sick patients to contacts.

**Carriers.** Ever since the importance of the carrier state in typhoid fever was

recognized, the air has resounded with the arguments of those who believe the carrier state to be of similar importance in other *Salmonella* infections (some say the total number of carriers (permanent) of all types is greater than the total number of typhoid carriers) and the rebuttals of those who believe that carriers are practically unknown in other *Salmonella* infections. Analysis of the available facts permits a few generalizations. This, it should be understood, is one area in which it is highly desirable to think separately of the paratyphoid organisms A, B, and C on the one hand and other *Salmonellae* on the other hand. In addition, incidentally, *S. choleraesuis* is unique in virtually never being found in healthy carriers.

In general, at least 2 to 4 per cent of the cases of paratyphoid fever may be expected to go on to chronic carrier status; that is, to excrete the organisms for more than one year. Thus, the carrier rate is probably at least as high as that in typhoid fever. In one outbreak among infants due to *S. paratyphi B*, one-third still had positive feces at six months. Other typical figures for the organism include 3 per cent at 6 months, 20 per cent at 6 months, 10 per cent at 3 months, 4 per cent or 5 per cent at 4 months. On the other hand, in *S. typhimurium* and probably in most *Salmonella* infections in which acute diarrhea is the chief complaint permanent carriers are relatively rare. It must be recalled, however, that other *Salmonella* infections are far commoner than the so-called paratyphoid fevers, and some people believe that as many as *one quarter of all permanent carriers are carriers of Salmonellae other than the paratyphoid*.

However, it is probably true for the paratyphoid as well as other *Salmonella* infections that the subclinical case and the convalescent carrier is numerically a more important source of infection than the permanent carrier. Salmonellosis can spread through a population in groups of clinical and subclinical cases, connected by transitory carriers.

There is some evidence that infants and children are more frequently carriers of *Salmonella* than adults and there is good evidence that infants carry the organisms on the average for a longer period of time. For example, following one *S. bovis-morbificans* outbreak, 60 per cent were positive after one month, 35 per cent after two months, and 2 per cent for longer than three months. All who carried longer than six weeks were under one year of age.

**Natural Distribution of *Salmonella* Types.** The bacteriology of the genus *Salmonella* is probably better understood than that of almost any other group of bacteria. This was not true a generation ago, and the validity of many early reports in the literature is seriously impaired by inevitable doubt as to what member of the genus was being discussed. The Kauffmann-White Schema, worked out in its final form about 10 years ago, is universally accepted. Biochemical analysis and analysis by means of somatic and flagellar antigens has been carried to a high degree of refinement. These advances, far from complicating the bacteriology of the *Salmonella* group, have rendered it simple and highly accurate. Experience, however, and well-trained technicians are indispensable in analytic procedures. Problems of species identification can be referred for final arbitration to a number of regional, national and international *Salmonella* centers.

The uses of antigenic analysis are varied, remarkable and sometimes ambiguous and controversial. For example, in the earlier days, it was believed that a fairly sharp correlation could be made between sero-types of *Salmonella* on the one hand,

and natural host on the other hand. Thus, there grew up the belief that some *Salmonellae* were predominantly animal types and others were predominantly human types with a few intermediate types of little, if any, host specificity. The typhoid bacillus represented one extreme of so-called adaptation to the human host and typhimurium was a favorite example of lack of host specificity. Continued effort has been made to assign each new sero-type a place on the spectrum extending between these two extremes. In addition to implications concerning the origin and host of sero-types, correlations were attempted between sero-type and various clinical pictures. The difficulties of these tasks proved so great that about 10 years ago a school of workers developed who gave up practically all such efforts and acknowledged that in essence, practically any *Salmonella* other than the typhoid bacillus and *S. pullorum* can exist in almost any animal species and, further, that it can cause various clinical syndromes.

However, with the improvements exemplified by the arrival on the scene of the Kauffmann-White Schema, it has gradually become clearer which correlations between sero-types, clinical picture and host range are valid, and which ones are not. It is now possible to outline, at least tentatively, the predominant patterns of distribution in nature by sero-type and the predominant clinical pictures by sero-types without going back to the older sharp division between animal and human sources.

Recent work has resulted in the following changes of some traditional concepts. Omitting typhoid from the discussion, the paratyphoid B can be said to be only *relatively* specific for humans; that is, to a much less degree than was formerly believed. For example, in the experience of Edwards and others (1948), *S. paratyphi B* was proportionately 25 times commoner in human sources than in animal sources. Nevertheless, it is important to notice that it was reported from five of the six nonhuman animal groups in this study. A refinement in identification methods indicates that tartrate negative *S. paratyphi B* is limited to human sources and is usually associated with an enteric fever syndrome. The tartrate positive variant is found in man and other animals and causes an acute gastroenteritis as its usual clinical manifestation. *S. paratyphi A* and *C* have been reported on extremely rare occasions in animals and appear to be primarily parasites of man.

As for the so-called "other *Salmonellae*," the animal adapted types, the investigations of the past decade have shown that the distribution in host species for practically all of these sero-types is far wider than was suspected previously. In general, a list of the 10 commonest sero-types isolated from animals will be practically identical with a list of the 10 organisms most frequently isolated from human sources in the same region. For the bulk of these organisms then, present evidence indicates that they are all relatively widespread in animal species and man; that any host specificity is relative and may appear largely as a result of selection of the sources of the strains isolated and identified.

Knowledge of the distribution of *Salmonella* types, both as to their frequency as the cause of human infections (Felsenfeld and Young, 1949) and as to their host range, is fragmentary. In the United States it has been derived from several different sources, each of which is selective in the material collected for study. The largest series of observations have come from the *Salmonella* diagnostic centers, such as that of Seligman and others (1946) in New York and Edwards and others (1948) in Lexington, Kentucky. Cultures are sent to these centers for typing and classifica-

on. Accordingly, it may be presumed that the cultures received would represent to an unusual degree the more severe clinical problems, the unusual sero-types and the geographic areas determined by the location of the laboratories and medical centers using this service.

When the information is derived from the experience of hospitals, it is again weighted by the more severe clinical cases and there is little precise information available regarding the population from which patients are drawn.

A third source of information is random and miscellaneous reports in medical and veterinary literature of the recovery and identification of *Salmonella* strains from human cases, market meat, canned milk and other foods, and from outbreaks of acute gastroenteritis. Because of this diversity and fragmentary character of available information it is difficult, if not impossible, to obtain an unbiased and comprehensive view of host relationships and distributions of *Salmonella* sero-types. Such a view can only be obtained by intensive field studies, conducted in a limited locality, as, for example, the one recently conducted in Hidalgo County, Texas. Here an attempt was made to systematically examine the human population for the presence of *Salmonella* types and to correlate these findings with the occurrence of diarrheal disease on the one hand and association with various domestic animals on the other. More such studies are needed before valid generalizations can be drawn.

**Clinical Manifestations.** In general, *Salmonellae* cause three types of diseases in individuals. They are best designated enteric fever, septicemia with or without focal manifestations, and gastroenteritis. A fourth category is the subclinical or asymptomatic infection.

It may be difficult to decide whether to call some cases enteric fever or severe gastroenteritis. Moreover, one form may merge into or be followed (with an interval of remission) by one of the other forms. Thus, for example, *S. paratyphi B* infections may be ushered in by an acute gastroenteritis followed by a quiescent interval of about one week and then develop into typical enteric fever; the Germans refer to the initial stage as *Vorkrankheit*.

The picture of paratyphoid enteric fever is essentially that of typhoid, though usually mild. The course is that of a septic fever with termination by lysis. Malaise, headache, arthralgia, are predominant manifestations. Rose spots may occur. There are usually no notable gastro-intestinal signs or symptoms but ulceration of the bowel may occur. The disease typically lasts two to three weeks and the case fatality rate is low.

Septicemia without focal manifestations is probably much more frequent in all salmonellosis, including enteric fever, gastroenteritis and subclinical cases than is often realized. For example, a goodly proportion of children in general hospitals with fever lasting a day or two and without other serious signs may show a transitory *Salmonella* bacteremia.

The septicemia of more clinical significance is that eventuating in such focal pathology as meningitis, pneumonia, arthritis, pyelonephritis, subcutaneous abscesses, etc. The case fatality rate is frequently high.

Acute gastroenteritis is the clinical picture commonly associated with so-called "food poisoning." The predominant symptoms are nausea, vomiting, diarrhea, abdominal cramps and headache. This condition usually lasts a few days with spontaneous recovery the rule.

*Salmonella* infection may be associated with chronic or recurrent diarrheas, but such evidence is very meager; so meager that coincidental rather than a causal relationship is suggested.

A special category of clinical salmonellosis that deserves mention includes those focal manifestations mimicking acute surgical emergencies. They occur rarely, but may be the occasion for serious therapeutic error as when unnecessary appendectomy or cholecystectomy is performed.

**Pathogenesis.** Very little is known of the pathogenesis and not much more of the pathology of salmonellosis. This much seems certain. It represents not an intoxication by preformed toxins in ingested material as was formerly thought, but a real infection which varies in degree and course according to host factors and parasite factors. Of these, the size of the initial dose seems to be one of the most important. The portal of entry appears to be the intestinal tract with lymphatic invasion. It is a fact that in one autopsy series on adults dying from various causes, *Salmonellae* were found in 16 per cent of the mesenteric lymph nodes. On the other hand, a high occurrence of positive cultures from the tonsils of children has suggested to some workers that an additional portal of entry may be the lymphatics of the pharynx. In any event, what happens following invasion of the intestinal lymphatics determines the clinical picture. In acute gastroenteritis presumably such invasion is itself minimal and limited. The intestine reacts violently by hypersecretion and hypermotility and in a matter of hours or days, the organisms are eliminated from the body. Alternatively, if invasion of the lymphatics is followed by invasion of the blood stream, positive blood cultures may result, but that does not necessarily mean that septicemic complications are inevitable. Positive blood cultures, even with an organism such as choleraesuis, which is undoubtedly more invasive and pathogenic than most other sero-types, are not always associated with severe clinical manifestations. In paratyphoid enteric fever, the pathogenesis and pathology are similar to that of typhoid fever.

**Incubation Period.** A considerable number of food-borne outbreaks of salmonellosis are on record in which it has been possible to determine the period elapsed between the time at which the group was exposed upon a common occasion or to a common foodstuff, and the onset of symptoms in the individuals affected. The minimum incubation period in these outbreaks has seldom been less than six hours, and the maximum period seldom more than 48 hours. In Feig's (1950) analysis, based upon 45 outbreaks, the mean was 18 hours, the interquartile range varied between 10 and 28 hours. The length of the incubation period in an outbreak of food poisoning frequently serves to distinguish those which are due to *Salmonella* contamination of the food and those which are due to staphylococcus or chemical poisons (see page 805).

**Frequency in Food Outbreaks.** In a recent analysis of outbreaks reported to the U. S. Public Health Service, 1945 to 1947, Feig (1950) found that in 476 outbreaks of gastroenteric disease in which effort was made to obtain the bacterial cause, 368 were attributed to staphylococci, 72 to *Salmonellae* and the rest to other organisms. In 42 of the outbreaks due to *Salmonellae* the species involved were determined. Sixteen were due to *S. typhimurium*; seven to *S. newport*; four to *S. oranienburg*, four to *S. montevideo*, two to *S. aniegar*, two to *S. newington*; and one

ach to *S. copenhagen*, *S. derby*, *S. choleraesuis*, *S. enteritidis*, *S. thompson*, *S. manhattan*, *S. panama*. In 56 of these outbreaks in which the contaminated vehicle had been determined by epidemiological investigation, the following frequencies were found: meat or meat products, 15; poultry, 10; bakery products, 8; potato salad, 1; eggs, 4; fish, 2; vegetables, 7; water, none; milk and milk products, 8; shellfish, 1.

**Control.** Basically, the rationale of control depends on how one visualizes the sources and spread of *Salmonella* organisms. When the animal reservoir of *Salmonellae* seemed all important and somewhat delimited, there was hope of blocking the natural sources. As it was realized how vast that animal reservoir is for practically all *Salmonella* types, that hope has diminished. In so far as the human carrier, especially the long-term carrier, is of importance, one may hope to break the chain of infection at that point. Elaborate precautions are legislated and sometimes enforced concerning the permanent carrier of paratyphoid organisms. At least one state has recently included in its provisions concerning occupational restriction, free cholecystectomy, etc., not only of paratyphoid carriers, but permanent carriers of any *Salmonella* sero-type. Routine examination of food handlers to detect carriers is being abandoned, for reasons of economy and common sense, almost everywhere. If human disease is propagated by direct contact between infected individuals and susceptible hosts, the clinical cases may be connected by chains of *temporary* convalescent or healthy carriers, which chains may sometimes be fairly long and continuous. The elimination of such contact is practically impossible to achieve except by the slow process of education in personal hygiene and improvement in the standard of living.

Granted that *Salmonellae* are widely distributed throughout the animal world, and granted that fundamentally man becomes infected because he ingests a material containing the organisms in sufficient numbers to establish infection, it is obvious that the lines of transmission must converge on the individual consumer of the contaminated material. Theoretically then, the place to attack with greatest hope of success is where the greatest convergence occurs, i.e., immediately before consumption of the material. That focuses attention on cooking, and traditionally thorough cooking has been advocated as a means of avoiding *Salmonella* infection. One trouble with this is that thorough cooking is very seldom described or defined. It is really quite simple. Thorough cooking means sufficiently high temperature to kill disease-causing organisms which might be present. Practically, this means cooking food in small containers or cooking meat in small pieces or cooking it hot enough or long enough to heat the center of the dish or the center of the piece. On a practical level, one cannot overemphasize the importance of this obvious item. Routine use of the meat thermometer, especially in restaurants and institutions where food is prepared in large quantities, is of real value. Cooks could be educated to read the death warrant of *Salmonellae* in the middle of any dish by the use of this inexpensive utensil.

Efforts to control *Salmonella* infection further back along the anus to mouth pathway are represented by the activities of the food inspectors and the veterinary problems involved. Routine antemortem inspection of food animals in most parts of this country has reached a sufficiently high level to eliminate a large number of animals sick with salmonellosis. But if it be granted that widespread invasion

of the tissues and organs of animals generally does not occur in the absence of clinical disease, then it follows that organisms are getting into food from slaughter houses and elsewhere from intestinal contamination. Some animals are fecal carriers and these cannot be detected by inspection.

A foodstuff currently of considerable importance in the *Salmonella* problem is egg powder. It is an excellent food and yet a very large proportion is contaminated with *Salmonellae*. Control of human disease from this source should be relatively simple. The basic fact is that while powdered egg is frequently contaminated, it is seldom heavily contaminated. The control implication is: teach the cook not to let reconstituted mixtures stand at room temperatures for very long, and secondly teach him to cook them thoroughly. The other point of attack is in the preparation of the powders themselves. Some form of pasteurization has been suggested and should be feasible. Counts can be significantly lowered by using clean eggs and by rapid reduction of the temperature of the egg meats after cracking.

The control of the water and milk supply need merely be mentioned. These two mechanisms for the mass dissemination of infectious agents are well protected in this country today and are no longer important sources of salmonellosis, if indeed they ever were.

The problem of salmonellosis spread by contact between an infected individual and a susceptible recipient is not essentially different from any other contact-spread disease. It is a matter of even greater attention being paid to personal hygiene and of increasing education in the population at large as to the importance of their personal sanitation. This is particularly important to emphasize in relation to those individuals who take care of sick patients. Nurses, physicians, ward attendants in hospitals have a particularly good opportunity to acquire contamination on their hands and spread this material to other individuals. Close attention to accepted handwashing technics will accomplish a great deal in the prevention of this type of transmission.

Community activities directed toward the control of arthropods in the name of prevention of salmonellosis are not justified on the basis of present evidence. As indicated above, many insects can spread these organisms effectively, but present indications are that they play a relatively minor role in the actual dissemination of the disease as it appears today. The same comment might be made with regard to rats and mice. These statements should not be taken as indicative of any lack of desire to eliminate these arthropod and rodent pests. They are simply to emphasize that there are other, and far more cogent reasons for the elimination of these nuisances than is their proven relationship to salmonellosis.

## SHIGELLOSIS

*(Bacillary Dysentery)*

JAMES WATT, M.D., DR.P.H.

The history of dysentery goes back to the remotest period accessible to historical inquiry. Dysentery is frequently mentioned in Hippocratic collections along with diarrhea. Indeed, Hippocrates himself indicated in the most definite way the close relationship of the diseases to one another in an epidemic. These associated conditions have been known throughout medical history as common afflictions of mankind and causes of great morbidity in civilian and military populations. In the accounts of pestilence by medieval historians and chroniclers, dysentery is most frequently mentioned after plague and pestilential fever. As Zinsser puts it in his "Rats, Lice and History": "Soldiers have rarely won wars. They more often mop up after the barrage of epidemics. Typhus with its brothers and sisters—plague, cholera, typhoid, dysentery—has decided more campaigns than Caesar, Hannibal, Napoleon and all the inspector generals of history. The epidemics get the blame for defeat, the generals get the credit for victory."

In the American Civil War, the annual morbidity rate attributed to dysentery in the northern armies was 876 per 1,000 and the death rate 10.3 per 1,000; and the situation was equally bad or worse in the southern army. During World War I it was a major problem in all of the armies. In World War II with greatly improved measures of military sanitation it was still in many areas the cause of a high non-effective rate. It is particularly notable that even in the Navy, with its excellent sanitary system, epidemics of dysentery occurred on ships at sea and off shore at Leyte Bay (Weil, 1947) and in Tokyo Bay (Thompson and White, 1946). In civil populations its relative importance as a cause of morbidity and mortality can only be surmised, since bacillary dysentery accounts for an indefinite proportion of the cases and deaths recorded under such diagnoses as diarrhea, summer diarrhea, diarrhea and enteritis, and dysentery unclassified. There can be no question, however, but that it has been one of the most important causes of death in infants and old people, among inmates of institutions, and among groups of the population living under primitive conditions. As enteric infections decreased in the United States, the incidence of diarrhea, dysentery and enteritis decreased at a slower rate than did typhoid.

The clinical distinction between dysentery and diarrhea has been maintained up to the present, though the difference is frequently one of severity rather than cause. In general, the term "dysentery" is applied to a febrile illness characterized by a sudden onset with abdominal pain and the passage of frequent stools containing blood and mucus accompanied by tenesmus. It may terminate either abruptly in death, within a few hours, or by gradual recovery, or rarely the disease may pass into a subacute or chronic state.

Toward the end of the nineteenth century, the clinical syndrome known as dysentery was found to have a dual etiology. It was established that one form of dysentery was due to amebae (*Entamoeba histolytica*). The other, and by far the commonest, form was found to have a bacterial etiology. In 1896, Shiga, studying an epidemic of dysentery in Japan, isolated the organism which now bears his name, and presented acceptable evidence of its etiological relationship. In 1900, Flexner, then a member of a commission sent out by the Johns Hopkins University to study the disease prevailing in the Philippine Islands, reported recovery from cases of dysentery of a bacillus closely resembling Shiga's organism. These observations were confirmed and extended by Strong and Musgrave working in Manila, by Krusé working in Germany and a succession of investigators. As additional nonmotile, Gram-negative rods were identified as having a causative relation to acute diarrheal diseases and their antigenic and biochemical structure was determined, it became apparent that there were several different species involved; all were included in the genus *Shigella*. Four principal groups, each composed of a number of sero-types have been recognized, viz., Group A *Shigella dysenteriae*, Group B *Shigella flexneri*, Group C *Shigella boydii* and Group D *Shigella sonnei* (Ewing, 1949).

**Diagnosis.** Since dysentery has a dual etiology, its differential diagnosis depends upon demonstration of the etiological agent. Moreover, there is a wide variation in the severity of clinical symptoms due to organisms of the *Shigella* group, ranging from fulminating attack of dysentery with fatal issue in a few days to a mild diarrhea, and diarrhea, in turn, merging with inapparent or subclinical infections. To designate this whole range of host reactions the term Shigellosis has recently come into use. Clinical criteria may provide a reasonably satisfactory working diagnosis for the treatment of an individual case, but a positive statement as to the etiology cannot be made on clinical grounds alone. Similarly, while the occurrence of cases of diarrhea and dysentery of sufficient severity to seek medical attention is usually an index of the prevalence of shigellosis in a community, an adequate idea of the distribution of these organisms in a population can be obtained only by bacteriological examinations made on a representative sample of persons who may or may not have recently been suffering from an attack of diarrheal disease. Prevalence rates are, therefore, dependent upon two principal factors: first, upon the care and thoroughness with which the bacteriological examinations are carried out, and second, on the selection of the groups that are examined, i.e., whether they be drawn from hospital and medical sources or whether they be drawn from the population at large.

Laboratory diagnosis by serological testing of the patient's serum for specific agglutinins is not a satisfactory procedure. Agglutinins are produced late in the disease and only in low titers. Moreover, the serum must be tested against a large number of type strains. The use of mixed strain suspensions reduces the chances of detecting antibodies present in low titers. The only satisfactory laboratory procedure is the fecal culture and isolation of the etiologic organism.

Two methods of obtaining and handling fecal specimens have been usually employed. The first is the collection of a small amount in a glass bottle half filled with preserving fluid. A preservative commonly used is 25 per cent glycerine in

normal saline buffered with disodium phosphate to give a pH of 7.4 to 7.5 after autoclave sterilization. The second method is to culture directly by rectal swab technique (Hardy and Watt, 1950). The development and use of highly selective culture media has markedly simplified the isolation of intestinal pathogens. In 1935, Zeifson developed a selective culture medium (desoxycholate citrate agar) which permitted for the first time large scale field studies, which have been so important in adding to our knowledge. Later, the *Shigella*-*Salmonella* (Difco), usually referred to as the SS agar, was found to be even more useful. After 18 to 24 hours of incubation at 37° C on selective media, suspicious colonies are picked to Russell's double or Krumwiede's triple sugar or Kligler's iron agar. The differential tube medium is examined after 16 to 20 hours incubation at 37° C. Final identification of the pure and species classification culture is established by cultural reactions and agglutinability with standardized poly- and monovalent typing sera. When carefully carried through by well-trained bacteriologists, dysentery bacilli can be recovered and identified from at least 70 per cent of infected persons. The failure to isolate *Shigella* from stools in acute diarrhea is more frequently related to the quality of laboratory work than it is to the actual presence of these organisms in the intestinal canal of the patient studied.

**Frequency of Shigellosis.** Investigations of shigellosis in the United States have, in general, followed two main patterns. Earlier studies began with the clinical case of *acute diarrheal disease* in hospitals and clinics. Bacteriological and clinical investigations were directed toward the determination of the etiology of individual cases, and of outbreaks in which the symptoms indicated an etiological entity. These diagnostic studies, taken as a whole, record a wide variation in the frequency with which *Shigellae* have been recovered from cases of illness. On the other hand, there is a remarkable similarity between the results of a few studies, particularly when one considers the tremendous difference in the methods available to each of the investigators. The common denominator of these studies appears to have been active participation by all the responsible personnel and meticulous efforts to assure the validity of a "negative" finding.

Flexner and Holt (1903) in eastern cities; TenBroeck and Norbury (1916) in Boston; Davison (1920) in Baltimore and Birmingham; McGinnis and others (1936) in Virginia; Cooper and others (1939); and Hardy and Watt (1948) in New Mexico and Georgia all showed that the majority of clinical illnesses classed as acute diarrhea were associated with the *Shigella* group of organisms. Since 1940, other areas have had similar investigations with similar results. It has thus been amply demonstrated that the principal agent found in severe acute diarrheal diseases is a member of the *Shigella* group. The qualifying adjective "severe" is extremely important to this generalization. (In this context, "severe" includes patients sufficiently ill to cause them to seek medical attention or, in the absence of good medical care, sufficiently ill to cause loss of time from work or play or an actual danger to life.) As living conditions have changed, statements of this nature must be more and more qualified according to regional conditions. A diarrheal disorder which would cause a great deal of concern to a mother or a pediatrician living in a modern city would be considered of relatively little significance by similar individuals living in an area where morbidity and mortality rates have not shown significant change during the past 50 years. This point must be kept firmly in mind when evaluating

statements about the acute diarrheal diseases and the frequency with which different causative agents are encountered.

The second general approach has been to study the frequency of *Shigella* infections in the general population. These studies have agreed with the clinical investigations mentioned above wherever it was possible to make direct comparisons. They have shown that where acute diarrheal diseases are a major health problem the *Shigella* group of organisms is associated with the majority of the severer illnesses.

**Carriers.** Further, they have shown that these illnesses constitute only a small number of the total infected individuals. It has been repeatedly demonstrated that for every person currently ill with *Shigella* infection, 8 to 10 other individuals in the immediate environment can be shown to have positive stool cultures but showing no symptoms of disease. This ratio of cases to subclinical infections varies considerably with age. In the very young it is rare for an individual to become infected without the development of clinical symptoms. As progressively older groups are considered, an increase is found in the frequency with which asymptomatic infections occur. One expects to find approximately five times as many subclinical infections per case in individuals over five years of age than is true in children under five.

A striking example of the frequency with which *Shigella* infection may go undetected is in a study carried out in New Mexico and Georgia. Three hundred and eighty individuals were found positive on surveys of the general population. These individuals had been examined simply because they lived in a chosen area and not because of any previous experience with diarrheal disease. Careful history revealed that only two of these people had been sufficiently ill to cause them to seek medical attention. Two hundred and thirty-nine could recall no illness at all. Thus, less than 1.0 per cent could have been detected by usual reporting methods through the practicing physician. Even if there were a complete record of all illnesses, approximately two-thirds of the infections would have been unrecognized since there was no associated illness.

There have been several studies of the duration of the carrier state in convalescence from a clinical or subclinical infection. The observations of Watt and others (1942) are pertinent in this connection. Serial stool examinations were made during the illness and at weekly intervals after recovery until three negatives had been obtained on a series of patients. Of 103 found positive during the illness, 82 were still positive at the time of clinical recovery. One week after recovery, 73 were still positive; the number gradually decreased until only seven were positive (or about 10 per cent of the original number) at the end of 10 weeks or more. Upon the basis of this experience and the observations of others, it may be stated that the average duration of the carrier state is about one month, but the organisms may persist in the intestinal tract of some individuals for several months. In a series of cases studied by Perry in 1925, 7 per cent of the patients harbored Flexner one year after their primary illness. Thus, occasional individuals may harbor *Shigella* for long periods of time, serving to carry the infection over in a community from one year to the next.

**Resistance.** Outside the human body *Shigella* organisms are extremely sensitive to environmental conditions and tend to die off rapidly. Even in feces they survive only for a short time. For this reason it is necessary to make bacteriological cul-

res as soon as possible after the specimen has been passed, unless a preservative has been added. Exposed to sunlight and drying the organisms die in a few minutes. They are easily destroyed by heat and chemical disinfectants. The importance of three factors must be recognized if any understanding of the epidemiology of shigellosis is to be achieved, viz., (1) the relative mildness of most of the clinical manifestations; (2) the relative frequency of asymptomatic infections; and (3) the relatively long duration of the carrier state.

**Types.** The original type discovered by Shiga produced a severe clinical illness and was different from the remainder of the group in that it elaborated a soluble exotoxin. This organism has been conspicuous for its absence in the United States during recent years in spite of the fact that it constituted a large proportion of the cases seen by early investigators (circa 1900). In addition to this decrease in the United States, there is an indication that the same type of change is taking place on a world-wide basis. They have been encountered so infrequently since the development of the selective culture media that no recent epidemiological studies have been made on shigellosis caused by *S. shiga*. Therefore, the distributions which have been observed pertain only to the other strains, Flexner, Sonne and Boyd. In general, epidemiological concepts are applicable to the group as a whole.

**Prevalence.** A tremendous variance exists in the frequency with which *Shigellae* can be found in the general population. In a recent study in New York City, from over 5,000 cultures in a normal population group, only two isolations of *Shigella* were made. In contrast, during a comparable period of time and using similar methods, some population groups in south Texas, south Georgia, New Mexico and California have been shown to have as high as 20 per cent of the individuals studied infected at one time. These rates are extremes, but illustrate the kind of variation which does take place within a single country.

An even more important variation is that which takes place within a much smaller geographical unit. Studies made of representative samples of the general population of a number of areas have shown that those families with good housing and those in the higher economic brackets show rates of *Shigella* prevalence not unlike those found in New York City; this in spite of the fact that only a few blocks away in another section of the same town prevalence rates of 15 to 20 per cent may be found.

**Season.** The high rates mentioned above usually occur in the general population during the spring, summer, or fall months, depending upon the section of the country. In general, the colder the winter months the later in the summer do high rates appear. In those section of the south where the winters are mild, a rise in *Shigella* prevalence usually occurs in April, May and June. In many of these areas this is followed by a sharp drop in prevalence in the summer months to be followed by a secondary rise in the fall. In areas where the seasons are more sharply differentiated, it is much more common to find a seasonal peak in mid to late summer. Prevalence studies have not been made in sufficient detail in tropical countries to permit a general description of variation in those areas. Such studies carried out under tropical conditions would be an important addition to our knowledge.

**Age.** *Shigella* infection shows a relatively characteristic age distribution in the general population of areas with a moderate to high endemic occurrence. Prevalence rates are low in the first six months of life, rising during the next six months

and reaching a level which remains relatively constant for several years. Beginning about the fourth year, there is a general decline in prevalence rates, reaching a second level about age 15. There are relatively unimportant variations after this time.

The age distribution of *clinical disease* produced by *Shigella* has a somewhat different pattern. It is relatively infrequent in the first few months of life, has its greatest frequency between 9 and 18 months and thereafter falls rapidly to a much lower level. Attack rates in young children are frequently 10 times those in adults. It is difficult to determine how much of this difference in age-specific attack rate is due to the greater resistance of the older individual to gastro-intestinal disturbances and how much is due to specific immunity acquired as a result of infection in early life. A study of household attack rates in New Mexico, Georgia and New York indicate that at least some of this difference is due to specific immunity. A comparison of the household attack rates in the Spanish-Americans and Indians (in general, a low income group) with the Anglo-American households (a significantly higher income group) showed that approximately twice as many older people developed clinical illness in the Anglo-Americans than was true in the Latin-Americans. A similar difference was observed between white and colored families in Georgia. White and colored groups in New York City, however, did not show such a difference and the attack rates were more nearly comparable to the better income groups in the south and west. These differences are best explained by the fact that in the south and in the west the lower income groups have a significantly greater amount of *Shigella* infections at all times than do the more fortunate residents of the area. In New York City, however, the prevalence of *Shigella* infections is extremely low and the opportunity to acquire infection is unlikely to occur even in the poorest households.

**Transmission.** *Shigellae* are spread naturally in a number of ways and the importance of these mechanisms of spread varies in different localities and times, either actually or relatively. The maintenance of a high level of *Shigella* infection in a group depends upon the more or less direct transfer of human feces containing *Shigella* from one individual to another. Therefore, any factor which tends to reduce the quantity of feces in circulation in a community will tend to reduce the amount of *Shigella* infection.

An illustration of this principle is readily apparent with respect to flies. Recent studies (Watt and Lindsay, 1948) have established that in *particular areas* fly control on a community-wide basis does result in a significant reduction of *Shigella* infection. However, an appreciable amount of shigellosis remained in these areas in spite of intensive efforts at fly control with chemical insecticides. A community with open privies, a large fly population and inadequately screened houses will present many opportunities for flies to become contaminated and to easily transport the infectious material to susceptible individuals. On the other hand, in a community in which human excrement is not left open to flies or in which the individuals are protected from flies by screening and the use of various household insecticides, flies can play only a minor role in the transmission of infectious material, since on the one hand they would not have access to such material, and on the other hand, they would not have access to the susceptible individuals necessary for a continuous chain of transmission.

Shigellosis has been shown to spread effectively in institutions, military groups and in some communities under circumstances which eliminated all of the avenues of dissemination except direct person-to-person transfer of fecal material. In most communities in which any one mechanism of spread has been reduced in importance, there has been a concomitant improvement in the general standard of living. This, in turn, results in important reductions in the ability of any other mechanism to function.

**Prevention and Control.** The reduction of shigellosis to the point of extinction is possible. This has been amply demonstrated by the virtual disappearance of these organisms from cities and rural areas which are modern in a sanitary sense. There remain, however, tremendous areas of the world and significantly large portions of the United States in which these modern developments have not yet occurred. Furthermore, unless there is a spectacular change in the rate of improvement, shigellosis will be a major problem in these areas for many years to come. In the meantime, however, it is important to use available resources in such a way as to obtain the greatest amount of control for the time and effort expended.

The preventive measures which can be expected to be valuable may be divided, for administrative purposes, into two major groups: (1) those which can and should be taken by individuals and (2) those which can be most effectively applied by community or group action.

The efficacy of *individual control measures* is directly related to the degree of understanding of the problem which has been achieved by the individual and the opportunity for carrying out the necessary precautions. Personal hygiene is a matter of no concern to an infant, nor is it of any concern to an adult who has lived his whole life in an environment lacking in basic sanitary facilities. An adult who has never seen a flush toilet can no more be expected to automatically use and maintain such equipment than an infant can be expected to use and maintain the same type of equipment. The infant learns by patient teaching on the part of the parent and this example must be followed in dealing with any population group suddenly afforded modern sanitary facilities. Handwashing to remove infectious material and thus prevent spread to others is another habit which is acquired through training. Further, these habits are practiced in inverse ratio to the difficulty involved in carrying out a particular action. Hands will be washed frequently and effectively only if running water is readily available. Therefore, individual preventive measures for diseases of this nature, although they must be carried out by each person, are dependent in part upon the effective installation of community utilities.

The *community measures* which are of greatest importance are the provision of a safe water supply made easily available to all members of the community. In thinking about a water supply to be provided to a community, it is customary to think of it as a foodstuff to be consumed by man; it can thereby act as a vehicle of dissemination of an infectious agent. Another role a water supply can play is frequently overlooked; it can also dilute and wash away infectious material. One can visualize a situation in which a lightly contaminated water supply could actually more than offset the cases of disease it spreads in its role as a foodstuff by the number of cases it prevented through serving as a cleansing agent and a remover of human wastes in a sanitary manner.

Safe removal of human excrement, preferably by a water-borne sewerage system,

is a second important factor. A third is the protection of foodstuffs distributed on a community-wide basis. This would include the provision of a safe milk supply, proper handling of foodstuffs in public eating places, and similar protective devices. The fourth community activity is the adequate removal and disposal of human and industrial wastes which constitute an important source of fly production. This latter, of course, is a combination of community and individual activity, since disposal and collection can best be done on a large scale and the care of individual properties must be the responsibility of an individual household.

It would seem that it would be unnecessary to add that all of these services must be made available at a cost which can be met by the poorest member of any community. Yet all too frequently, municipal ordinances require sewer connections for all residents but no sewer lines are available for house connections. In other cases the sewer lines may be present but the cost of making such a connection is prohibitive because of the low income of some of the people served. It is in situations of this sort that shigellosis is still taking a major toll of life and health in this country today. Problems of this sort can and have been solved in communities on their own initiative whenever a sense of local responsibility has been developed on a community-wide basis. Furthermore, experience demonstrates conclusively that with an improved standard of living, and the opportunity and desire on the part of the population to devote some attention to personal and community hygiene, shigellosis cannot maintain its position as an important cause of human disease.

In the event of an epidemic in an institutional, military or civilian community, individuals with a diarrheal disorder should be placed under medical supervision as rapidly as they can be discovered. Broad spectrum antibiotics are effective in treatment and significantly shorten the carrier state. Some sulfonamide preparations are also useful. Institutional outbreaks can be controlled by effective use of one or more of these drugs. Except under unusual circumstances it is not worth while to try to discover carriers. If the outbreak is explosive in character, suggesting infection of a group of individuals by a common medium, investigation of food, water and milk supplies should be immediately instituted. At the same time, every effort should be made to reduce the opportunities for person-to-person propagation of fecal material by direct or indirect contact through appropriate sanitary and hygienic measures.

The possibility of using mixed bacterial vaccines has been under investigation for many years. None of the preparations so far produced has proved effective in development of active immunity when treated under field conditions. There is still much that remains unknown about the nature of the immunity to *Shigella* infection.

## DISEASES AND INFECTIONS DUE TO INTESTINAL PROTOZOA

GILBERT F. OTTO, Sc.D.

## AMEBIASIS

(Amebic Dysentery)

Amebiasis is a chronic infection of which the so-called classical amebic dysentery is only one clinical entity. Amebiasis is usually visualized as a tropical infection but it is interesting to note that it was first discovered by Losch, in 1875, in a patient in St. Petersburg (Leningrad), U.S.S.R., who had just come from Archangel, even farther north. The infection is now known to occur widely in both the north and south temperate zones. In general, however, it is more common and clinical amebiasis more frequent in the sub-tropics and tropics.

**Host Reaction.** The causative organism is *Entamoeba histolytica* \* which lives primarily in the colon. Hegner found evidence in monkeys that they could colonize and multiply in the lumen, i.e., in the fecal content of the colon. Craig, on the other hand, was convinced that the infection does not persist without some tissue invasion. In support of this postulate he summarizes his own observations and the reports of Johnson, Faust, and others, and even some of Hegner's experiments, which demonstrate that small, almost pinpoint lesions, and even extensive invasions of the tissues occur in the colon of both man and experimental animals in the absence of any demonstrable clinical evidence of such pathology. It is implied that a more extensive and adequate search of the post-mortem colon could hardly fail to demonstrate, at least, microscopic lesions in those who harbor the organism. Craig states that over half of the so-called "carriers" have histories of the symptoms of amebiasis.

\* The spelling of *Endamoeba* for the generic name which has been so commonly used in American medical literature is an error due to confusion with *Endamoeba blattae* (Butschli, 1878) Leidy, 1879. *Entamoeba histolytica* and *Endamoeba blattae* are not in the same genus. The similarity in the spelling of these two generic names is unfortunate. For details see Kirby (J. Parasitol. 31:177, 1945) and Stoll (Opinion 312, Internation. Comm. on Zool. Nomenclature, Am. J. Trop. Med. Hyg., 4:376, 1955).

Sapero, in 1939, reported an objective study in which histories were taken and physical examinations were done on 450 apparently healthy Navy personnel in Panama, while fecal examinations were made independently on the same group of men. Of the 106 who were found to harbor *E. histolytica*, 43 per cent had symptoms suggestive of amebiasis whereas only 23 per cent of those in which *E. histolytica* was not found presented such symptoms. Abdominal distress and demonstrated localized abdominal tenderness were most frequently found. Localization in many cases suggested chronic or subacute appendicitis, which is a symptom-complex commonly developed in both chronic and acute amebiasis.\* However, Sapero's findings also demonstrate that many individuals harbor the infection without sufficient ill effects to lead them to consult a physician. The infection may, and in many cases obviously does, follow an insidious course. Recurrent crops of minute lesions may produce no sign of illness, but extension in number and size of these lesions may produce ill defined abdominal distress and tenderness; still further extension of the lesions or perhaps delay in healing may produce the frankly chronic cases of amebiasis; and still further extensions of such lesions may produce the acute dysentery. Extra-intestinal extension of the lesions most commonly occurs in the liver and evidence is accumulating to indicate that this is more common than formerly appreciated.

Although there may be some tissue invasion in most, if not all, infections with *E. histolytica*, one should not lose sight of the fact that most infected individuals in the temperate zones and many in the tropics are unaware of their infections until apprised of the fact from routine survey examinations.

Since most infections appear to be asymptomatic or mildly pathogenic, much consideration has been given to how these differ from the comparatively few in the temperate zone or the somewhat larger portion in the tropics who obviously suffer from the disease. Various strains or races of this organism have been postulated and it is even suggested that *E. histolytica* may in reality be a complex of several almost indistinguishable species. Sapero and others (1942) reported that in their series of 283 cases in Panama the cyst fell into two distinct size categories, that in 57 per cent of the cases only the large race (11-12 $\mu$ ) were found, in 37 per cent only small race (7-9 $\mu$ ), and in only 6 per cent were both found. In the latter group the organisms seen fell distinctly into a bimodal distribution, suggesting double infections and not intermediate forms with large and small extremes. Furthermore, in a number of cases followed over several months from the period of illness through apparent convalescence and clinical remission, the parasites remained consistently of the same size throughout. In all these cases the large race was present exclusively. In most other studies there have been no references to the size of the organism but in the limited studies in which size has been determined only the large race has been found present in patients suffering from clinical amebiasis. A number of workers have shown that the large race taken from clinical cases of amebiasis become more readily established in laboratory animals and produce more extensive lesions than do the small race taken from asymptomatic individuals. Some evidence has been presented also which suggests that there may be two or more races or strains which differ antigenically one from the other, but these have not been correlated with

\* In the Chicago epidemic, surgical intervention in amebiasis simulating surgical conditions was associated with a 50 per cent mortality rate.

It cannot be unequivocally denied that the larger size and greater virulence result from the rapid transfer of *E. histolytica* through susceptible hosts or rapid development in a particularly susceptible host. Since the two races, if they are genetically distinct races, can be distinguished only on the basis of size and possibly by the critical use of experimental animals, it is generally considered impractical, if not presumptive, to attempt such distinction in routine examinations.

**Laboratory Diagnosis.** Those with extensive experience with amebiasis generally agree that fecal examination is the most satisfactory means of establishing a diagnosis of the amebic colitis or amebic dysentery. As many as 10 or more different stools over a period of two or more weeks may be required to demonstrate the parasite. Even with the aid of the good illustrations and classical descriptions in most of the readily available books on parasitology or laboratory methods, the recognition of these forms is not easy. Even the experienced technician may have difficulty in identifying them, and the isolated technician without opportunity for interchange with experienced personnel is frequently in difficulty and may fall into a pattern of chronic error. Thus, in the temperate zones where clinical amebiasis is not commonly seen, the laboratory may completely miss the few cases on which aid is sought. A number of cases, including some fatal cases, in the Chicago epidemic were not correctly diagnosed because of the omission of or inadequacy of laboratory examinations. Even more commonly the unsuspecting patient is committed to a course of treatment for amebiasis while the actual cause of his illness is not discovered because harmless amebae or even epithelial cells have been mistaken for *E. histolytica*. More than once a community has become concerned over a large number of "active cases of amebiasis" found by these means and several epidemics have been arrested" by correcting the laboratory diagnosis.

In view of the difficulty in maintaining adequately trained and experimental technicians in areas where amebiasis is not a major problem, a simple serological test employing standard technics would be a very useful tool. It has been suggested that a positive complement fixation might also distinguish between the case with colonic lesions and those who harbor the infection with little or no tissue invasion. There is, however, no evidence so far to support this hope. In spite of the intensified study of the serological aspects of amebiasis both at home and abroad in the past quarter of a century, there is still no clearly demonstrated use for such tests in colonic amebiasis. However, recent work by Terry and Bozicevich and by Massey and Brown (1950) have shown that the complement-fixation reaction may help resolve any suspicion of amebic hepatitis. This is significant because hepatic infections may persist in the absence of sufficient current colonic infection to produce cysts in the stools.

Two separate stages of the parasite are recognized:

**TROPHOZOITE.** The active *trophozoite* or vegetative stage is the biologically active stage. It is the stage which invades the tissues, feeds, and multiplies rapidly by binary fission. Once the infection is established, it is maintained and spread principally, if not exclusively, by the trophozoites through direct extension of established lesions and the initiation of new lesions by trophozoites discharged into the lumen of the colon or transported through the vascular network. However, the trophozoites are ill adapted for survival in the external environment or for passage through the acid condition of the stomach. While infections have been established

experimentally by massive feedings of fresh trophozoites there is nothing to suggest that they are in any way involved in the natural transmission of the disease.

**THE CYST.** The cyst has a heavy resistant wall and is well adapted for survival outside the body. There is no evidence that cysts are formed within the tissues, but rather they appear to be formed exclusively in the lumen of the colon from trophozoites discharged from the lesions. While it is not impossible that excystation may occur with the same host in which the cyst is formed, the available evidence suggests that this does not normally occur. There is some reason to believe that this stage requires exposure to external environmental conditions before it can excyst. It is probable that in addition to serving as a transfer stage, the cyst stage is part of the process of biological rejuvenation. The newly formed cyst is uninucleate, but two nuclear divisions while in the alimentary canal, result in the typical quadrinucleate cyst in the normal stool. Within a dysenteric, diarrheic, or otherwise loose or mushy stool any or all gradations may be found from the trophozoite, through pre-cysts to uninucleate, binucleate, trinucleate, or quadrinucleate cysts.

While the cysts of *E. histolytica* are provided with a protecting wall, they are really not prepared for survival under extremely adverse circumstances. They are not remotely comparable in this respect to such structures as the spores of fungi. They are quickly killed by drying or by the ultraviolet rays of the sun. Moisture is required for their survival and in water the length of time they will survive is limited by temperature. The infection is particularly common in the tropics and, therefore one may assume that conditions in the tropics enhance the transmission. Nevertheless, the cysts survive longer at freezing than at any higher temperature. One comparative study by Philpitschenko revealed a survival of three months at  $-20^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$ ); one month at  $0^{\circ}\text{C}$ ; 14-17 days at  $13^{\circ}\text{--}17^{\circ}\text{C}$ ; and only 24 to 48 hours at  $34^{\circ}\text{--}37^{\circ}\text{C}$ . The results reported by different workers under different conditions extend or decrease the time of survival in individual experiments but the relationship of decreasing survival time with increases in temperature above freezing is consistent. Survival up to one year at freezing has been reported but most workers have not succeeded in keeping them alive for more than a few weeks at room temperature ( $20^{\circ}\text{--}25^{\circ}\text{C}$ ) and above  $30^{\circ}\text{C}$  death is progressively more rapid with survival at  $45^{\circ}\text{C}$  being only a matter of minutes, and  $55^{\circ}\text{C}$  only a matter of seconds.

**Conditions of Transmission and Prevalence.** Thus, other things being equal, it would appear that the temperate zones and even the Arctic offer more favorable temperatures than the tropics for the survival and dissemination of the cyst of *E. histolytica*. Since this infection, like the bacterial enteritides is feces-borne, its dissemination requires an ample supply of undisposed feces from which man may directly or indirectly obtain his infection. A superficial study of scatology will quickly reveal that carelessness in fecal disposal increases rapidly as one moves within the United States from the northern states to the semi-tropical southern states. In many areas of the tropics there is essentially no attempt at sanitary disposal of feces. The rough correlation between unsanitary fecal disposal and the prevalence of amebic infection along broad geographical lines is further refined by considering the different types of populations within these various areas. Table 3-8 gives the results of a series of representative surveys of three different types of population in various parts of the United States. The prevalence of *E. histolytica* is low in college students, from New England (New Hampshire) to the deep south (New

Table 3-8. Comparison of the prevalence of *Entamoeba histolytica* in college students, rural populations and institutional populations in the United States

Area	Authority	Per Cent Positive
A. College Students		
New Orleans, Louisiana	Faust (1942)	8.3
" " "	Swartzwelder (1938)	3.1
Athens, Georgia	Byrd (1936)	5.2
Area, Kentucky	Headles and Cable (1942)	5.0
. Louis, Missouri	Tsuchiya and Jean (1940)	2.1
Philadelphia, Pennsylvania	Wenrich, Stabler and Arnett	4.1
Portsmouth, New Hampshire	Connell and French (1939)	1.4
B. Rural Populations		
Georgia	Seckinger (1936)	20.5
Tennessee	Meleney (1930)	17.3
"	Milam and Meleney (1931)	36.4
Virginia	Faust (1930)	20.0
Oklahoma	McMullen and Gray (1941)	10.0
New Mexico (Indian Reservation)	Spector and Hardy (1939)	25.9
Wyoming (Indian Children)	Owen, Honess and Simon (1934)	26.5
C. Institutional Groups		
New Orleans, La. (Orphanage)	Faust (1931)	55.5
Georgia (Mental Hospital)	Reardon (1941)	40.0
Maryland	Armaghan and Meeliary (1938)	13.6
(School for Feeble-minded)	Faust (1931)	13.8
New Jersey (Mental Hospital)		

Rearranged from Craig, 1944, table 3.

Orleans). On the other hand, it is just as high among the rural Indians of the arid west (New Mexico) and the far north (Wyoming) as it is among the rural population of southeastern United States. The highest infection rates are found in the unsanitary institutionalized groups (orphanages and mental hospitals). The gradient of infection in these three groups is roughly parallel to the gradient of unprotected fecal concentration near or in living quarters. There can be no question that the group of college students live under conditions where promiscuous defecation is not the rule. Although they are drawn from all groups of the population, the higher economic levels with better methods of fecal disposal, are much more commonly represented than are the lower economic groups. Among the lower economic groups in the rural population, small villages, and even in the cities of southern United States, toilet facilities, even when available, are relatively little used by children and indifferently used by adults. In every state in the southeastern United States there are many rural homes of the economically poorer groups without any structural provision for fecal disposal, and a significant number of public schools without such provision. The net result is fecal deposition at the site of immediate convenience and visual record of this is provided in the yards of many homes. In such an environment the indifference extends somewhat up the economic scale. One rural school board, drawn from the economically more stable elements of the population and whose members had children in the school, solemnly advised that they had carefully

considered constructing a sanitary privy and had concluded that the odor of concentrated feces not only would discourage its use but would constitute a greater nuisance than random defecation around the school house.

In an institution such as an orphanage even a nominal amount of violation of sanitary concepts may provide ample sources of fecal contamination in the midst of this congested population. Gross carelessness in fecal disposal which may take place in orphanages, and commonly does in mental institutions, provides the maximum concentration of feces in the midst of a population concentration.

Thus, the highest concentrations of unconfined feces appears to provide the opportunity of the greatest amount of transmission and the highest prevalence rate of amebiasis. Under these circumstances there is ample opportunity for direct contamination of hands, food and even drink. It is difficult under these circumstances to determine the exact vehicle of transmission. Nevertheless, less direct methods of contamination should be carefully considered for an understanding of the epidemiology of this infection.

**RAW VEGETABLES.** Wherever human feces is used as fertilizer in truck farming the resulting vegetables, particularly leafy vegetables such as lettuce, appear to constitute a possible source of infection. One should keep in mind, however, that much of the night soil is accumulated in storage jars before being applied to the crops and that many cysts are killed in this storage. Many more of the cysts which reach the leaves as the night soil is applied to the crops do not survive the subsequent period of growth before the crop is marketed. Thus, contamination of the vegetables with viable cysts is more likely to occur during harvesting or in subsequent handling even in an unsanitary kitchen. Among the Chinese, amebiasis is concentrated in family units and appears to be mainly associated, as in the southern United States with dooryard pollution by young children. Thus, any food, leafy vegetables included, may become contaminated where the sanitary conditions are generally poor.

**FOOD HANDLERS.** The infected food handler logically comes under suspicion with any enteric infection and can not be totally discounted in the transmission of amebiasis. Nevertheless, the available data are at least ambiguous. In the Chicago epidemic the food handlers, as well as other employees, in the incriminated hotel showed a high rate of infection. It is probable that they, as well as the guests, were the victims of the contaminated water and, while they may have contributed to the contamination of the water, there was nothing to suggest that they disseminated the infection through the handling of food. The gross contamination of the water in this situation may, of course, have masked any subtle role of the food handlers in the epidemic. It has been suggested that the familial distribution of the infection in the rural areas of southeastern United States may have resulted from the infected housewife in her role as a food handler. In view of the widespread fecal contamination in such areas nothing as subtle as this is needed to explain the familial distribution. Furthermore, both ascaris and hookworm have such familial distributions in these areas and neither could be transmitted directly from an infected individual through immediate food contamination since both require a protracted period of development in the soil. Schoenleber (1940) reported a 90 per cent reduction in both the colonization rate and the infection rate with *E. histolytica* as a result of treating infected food handlers, apparently also treating those in the general population who were infected, and enforcing improved personal hygiene and general sanitation in the handling of food.

mention is made of what other improvements may have been accomplished in general use of the available sanitary facilities. The results were truly remarkable and it is unfortunate that only those data are presented which seem to support his previous conviction that the infected food handlers were exclusively responsible for the transmission of the infection.

Sapero and Johnson considered the possible role of the infected food handlers in spreading the infection among naval personnel. In their series, officers and enlisted men served by infected food handlers actually had a lower infection rate than those served by noninfected food handlers. In neither group was the infection rate higher than that to be expected in the United States. It seems evident then that with good kitchen and mess practices, infected food handlers do not constitute any immediate source of infection.

**FLIES.** It has been amply demonstrated that flies and other insects are capable of carrying and discharging viable cysts. Viable cysts have been found in the vomitus of flies and in the feces of both flies and cockroaches as much as two days after they were ingested. It is commonly assumed, therefore, that flies can and do transmit the infection in nature. The prevalence of flies in unsanitary areas, particularly in the tropics, is often cited as supporting the theory of fly transmission. Again, as with the postulate with respect to infected food handlers, there seems to be a significant regard for the more direct and immediate contamination of food and drink. Craig reported an outbreak of amebiasis in 1916 among troops serving along the Mexican border at El Paso, Texas, coincidental with an increased fly population. It is possible that flies played a role in the transmission of the infection but it is not clearly demonstrated. The fact that flies and the disease rate followed the same time curve does not allow for the usually extended incubation period in amebiasis.

Certainly in many areas flies, though abundant, fail to transmit the infection. Thus, along the Mediterranean coast of North Africa the high temperature and the dry winds destroy cysts if they do not reach a moist medium quickly. Sanitation is conspicuously lacking and flies are abundant with ample opportunity for traffic between feces and food. If flies play an important role in the transmission of this infection it is difficult to see why the amebic dysentery of tropical Africa should give way in much of North Africa to bacillary dysentery and other bacterial enteritides.

Certainly, flies and other insects can provide the means for the contamination of food and drink. However, the basic question in the epidemiology of amebiasis is, with any other enteric disease: Do they do this with sufficient regularity and sufficient volume to constitute a significant factor in the maintenance of the endemicity or the production of epidemics of amebiasis?

**WATER.** This medium must be seriously considered as a vehicle for the ingestion of the amebic cysts and a number of workers in the field feel this is the most important means of transmission. Accordingly, there has been a great deal of experimental investigation of cysts in water. It has already been noted that they survive longer in cold water than in water at summer temperatures, with rapidly shortening periods of survival as temperatures move above 25° or 30° C. Since the specific gravity of the cysts is not much above that of water they settle slowly, about an inch or two per hour in distilled water and more slowly when appreciable amounts of solutes or suspended organic material are present. Even in distilled water they are uninjured by the amounts of chlorine normally added to modern city water to protect against

bacterial contaminants and are at best only slowly killed in amounts of chlorine or iodine which render water unpalatable. Thus, cysts within water can remain available and viable for some time after contamination of the water. However, within a matter of days many of the cysts are lost by death or settling or both. If water is to remain a continued source of infection it requires a constantly recurring source of direct and heavy fecal contamination.

Apparently the transmission of amebiasis has been directly traced to water on only four occasions. Cysts were not recovered from the water, nor were they sought, but the gross fecal contamination of the water on each occasion leaves little room for doubt as to the cause of the outbreak. In the first of these, an epidemic in 1933 and 1934, traced to two Chicago hotels, three sources of direct and continuous fecal contamination were found, back siphonage from toilets, drainage from a defective sewer over the unclosed water cooler, and direct cross connections between sewer lines and water supply. Nevertheless, the attack rate was comparatively low in those with a short exposure as indicated below:

Duration of Stay in Days	Clinical Amebiasis per 1,000 Guests
1 . . . . .	3
7 . . . . .	11
8-14 . . . . .	13
30-90 . . . . .	111

The data, as Craig points out, are in accord with the view that large numbers of organisms are required to initiate an infection. Even with this massive exposure, the incubation period was 5 to 16 weeks for half of the cases, incubation periods for less than a week were reported in only 6 per cent of the cases. Under similar circumstances, an outbreak of diarrhea in the Mantetsu Apartment Building in Tokyo led to a prompt investigation (Davis and Ritchie, 1948). Sewage from a tank in the sub-basement had overflowed and submerged the main water line which was leaking and intermittently under negative pressure. Corrections were made before critical illness or deaths occurred but 63 per cent of the Americans quartered in the hotel and 22 per cent of their Japanese domestics became infected. The third example of this type is furnished by firemen in Chicago. Those fighting the stockyard fire in 1934 drank from the mixture of sewage used to fight the fire and 58 per cent were found to have *E. histolytica* as compared to 15 per cent in other firemen in the city. The fourth and most recent example occurred in a factory in South Bend, Indiana, during 1952-53. In this case a leak in the water line at a point where it was under negative pressure and submerged in sewage again provided for a continuing supply of direct fecal contamination in the drinking water. At least 30 cases (an attack rate of over 20 per 1,000), 2 deaths, and an infection rate of about 50 per cent developed before the situation was brought under control (Offutt and others, 1955).

Obviously, water can be the vehicle for transmitting the infection. Wykoff and others (1955) have called attention to the possible epidemiological significance of open wells as a more diffuse source of water-borne amebiasis in the Kofu Valley of Japan. However, the only direct incrimination of water as a source of infection has been under circumstances, outlined in the preceding paragraph, which provided for extraordinarily heavy, direct and almost continuous contamination of the drinking water with fresh sewage.

**MASS EXPOSURE: SUMMARY.** The preceding points have been considered in more detail than is usual in such a text for the dual purpose of making it clear that flies, infected food handlers, and drinking water are all capable of carrying the infection to man and to emphasize that there are not sufficient data available to determine the part they play either in maintaining the infection in any endemic area or in producing epidemics. Theoretically, it should be possible to establish the infection in a given individual with a single cyst. Actually, the direct feeding of a great many cysts to man or experimental animals may fail to establish the infection. Walker and Sellards established infections in only 18 out of 20 human volunteers who received thousands of viable parasites; one of the 18 required three such feedings. Furthermore, the infection was sufficiently severe to produce clinical amebiasis in only four. Recently, Taylor and his co-workers (1950) reported that injecting 1000 to 250,000 amebae intracably produced lesions in only 58 of the normal guinea pigs used. Sadun and others (1950) found that no infection resulted from more than 1,000 organisms and in only 1 out of 8 with 5,000; increasing percentages became infected with higher doses, but even at doses of 2.5 and 5 million not all guinea pigs became infected.

Both the laboratory and field observations emphasized that massive exposure is required to establish the infection in a large percentage of the population. Only in the tropics and subtropics with their climatic encouragement of promiscuous defecation, and under such specialized circumstances as in the Chicago epidemic, or the filthy conditions in some mental institutions, are highly endemic conditions maintained or epidemics developed with high morbidity and mortality rates. Except under special circumstances, such as the Chicago epidemic, it is impossible to determine whether food or water is the immediate source of the individual infection. In much of rural southeastern United States fecal material is more commonly found closer to the house than to the well or spring with the result that children, at least, playing and usually eating in contaminated yards, would have ample opportunity for immediate infection. As one moves from the endemic areas, sanitary conditions are, in general, better and the more subtle influence of flies and infected food handlers may help to maintain the generally low infection rate, with relatively little frank disease. However, one should not disregard the fact that even in cities, such as Baltimore and New York, there are elements of the population who have little or no regard for the sanitary code. The generally cooler climate in such cities provides for longer survival of the cysts than in such cities in the south and in part compensates for the smaller amount of fecal contamination.

**Immunity, Malnutrition, and Concurrent Infection.** There is no evidence in man or domesticated animals that a highly protective immunity develops as a result of the infection. Conversely, the disease is characterized by chronicity and relapse. Subclinical infections may persist for years; the writer and his colleagues had one infected animal attendant under observation who continued to discharge parasites in his feces for over a decade. However, this should not be interpreted to mean that there is no immune response. It seems probable that a low grade immunity keeps the infection under partial control and clinical breakthrough results from a temporary reduction in that immunity. Recently, Swartzwelder and Muller (1950) have shown that the injection of saline extract of *E. histolytica* into young rats before infection induced a significant degree of protection. Not only was complete protec-

tion against infection provided for a third of the rats but the observed lesion in those which became infected were only about half as extensive as in the controls. There is as yet no evidence that this has any practical value in human amebiasis but it does support the postulate that there is, at least, a low level of immune response in amebiasis. The possible significance of such immunity on the epidemiology and clinical course of amebiasis is extremely difficult to ascertain at the present state of knowledge.

It is commonly believed that resistance to the infection is lowered by malnutrition. The precise manner in which it occurs is not clear. It may in part reduce the body's capacity to respond immunologically. The most concise evidence of the possible role of malnutrition is afforded by experimental studies. Faust found that dogs on a balanced diet were more resistant to *E. histolytica* infection than those receiving a diet of salmon. Both liver and liver extracts were found to increase the resistance and would actually appear to be curative when fed to an animal suffering from acute dysentery. More recently, Taylor and others (1950) have found that diet has a powerful influence on the susceptibility of guinea pigs to *E. histolytica*. Reports from southern France have related increased *E. histolytica* infection to malnutrition during the war and postwar period. Over a quarter of a century ago, Fletcher and Jepps classified amebiasis in Malaya as a disease of poverty and want and noted that "dysentery vanishes before comfort and prosperity."

What role accompanying bacteria play in the production of clinical amebiasis is not clear. However, the recent report by Phillips and others that they were unable to produce amebiasis in germ free guinea pigs unless bacteria accompanied the amebae is of more than passing interest.

**Imported Amebae.** During both World Wars I and II troops from the temperate zones of Europe and America suffered significantly from amebiasis in the tropics. Concern has been felt over the possible aftermath of such infections in returning troops, both over possible relapsing amebiasis in the returning personnel and the possible transmission of the infections to the home population. Following World War I neither problem was encountered. In the present postwar period a number of veterans have required medical attention. The Veterans Administration reports the annual discharge of over 1,200 patients, admitted primarily for amebiasis in 1947 and 1948. However, routine surveys among nonhospitalized veterans have failed to demonstrate a generally high infection rate; from 3 to 10 per cent, which is not materially higher than the civilian population from which they were drawn. Lincicome and others (1950) compared the infection rate of veteran and non-veteran students at the University of Wisconsin with the following results:

642 veterans with overseas' service . . . . .	4.5%
282 veterans serving only in United States . . . . .	2.5%
184 nonveteran students . . . . .	1.6%

Further analysis of these data show a somewhat higher prevalence among veterans with tropical service. Other surveys have shown as much as 20 per cent in personnel from the China Burma India Theater. That these constitute a threat to the home populations seems very unlikely. If such veterans return to communities with poor sanitary habits and revert to the local habits, they will, of course, contribute their share to the community infection, but in such areas the infection is already high.

It is doubtful whether they can materially alter it. With good sanitary habits in the area they are no source of danger and where sanitation is generally good the danger is nil. These postulates are supported by the vital statistics which show no year increase in amebiasis among the civilian population.

**Control.** In a modern city the purification and treatment process of water is sufficient to insure its freedom from infection when it leaves the city mains. Its drinking thereafter may be considered a source of concern only under such gross abuse as characterized the Chicago epidemic or when otherwise contaminated after passing the faucet. Under such circumstances the dangers are not alone from amebiasis. The maintenance of sanitary handling of food, including fly, roach and insect control, in every stage of its preparation should not be dependent upon the possible danger from amebiasis. Lapses in these concepts may account for some of the subclinical amebic infection seen in the temperate zone. It is improbable that one can escape a nominal amount of exposure indefinitely but continued stress of good sanitary practice in handling food and water should contribute further to the reduction of the infection in the temperate zones. Specific attempts to prevent employment in food handling of individuals with *E. histolytica* infections has not been successful. It has been pointed out by the Committee on Amebiasis of the American Society of Tropical Medicine that such an individual constitutes no special hazard if he obeys the simplest concepts of personal hygiene and cleanliness. This committee and the U. S. Public Health Service have, therefore, recommended that efforts, legal and educational, be concentrated on the provision of adequate toilet and washing facilities and insistence on their use. It is further recommended that regulations designed to detect the infected food handler be eliminated, since medical certificates are commonly issued on superficial physical examination. The subclinical infection cannot be detected without fecal examination and to generally require such examinations would be costly, lead to deception and result in a false sense of security. Among military personnel or in specialized civilian installations in the tropics the periodic fecal examination of food handlers may have some value as an educational and disciplinary step. It would thus be significant only if used as one step in improving kitchen and mess hall sanitation.

A possible problem for correction in connection with large cities is the growing use of sludge from sewage disposal plants for fertilizer. However, both on theoretical grounds and the direct observations of Cram one may feel assured that the sludge resulting from a modern sewage disposal plant does not constitute a source of infection with *E. histolytica*.

Any attempt to reduce the transmission of amebiasis among the local population within an endemic area must take cognizance of the economic, sociological, and educational background. Customs and habits are a reflection of this background and are deeply entrenched. Sanitary improvements will come slowly and the process can be accelerated only to a very nominal degree. The significant problem of control, therefore, centers around protecting individuals or groups who may be transient, semipermanent, or permanent residents in the area. This would include military populations. When such groups, either civilian or military, are living together in a community and are large enough to either directly influence the sanitary control of food and water, or to provide their own installations of modern design, the principles that follow are not basically different from that in a modern city; these must be

adjusted around the local problems of source of supply. It is generally accepted that leafy vegetables such as lettuce raised and eaten where human feces is used as fertilizer may require treatment immediately before consumption to render them safe. The leaves of such vegetables should be separated and thoroughly washed with water. Attempts to enhance the cleaning effect of such washing by the addition of detergents or to kill cysts with chlorine or iodine preparations have not proved satisfactory. Therefore, even when eaten "raw" such vegetables should have a minimum period of heat treatment: either a brief immersion (less than a minute) in water above 80° C or longer immersion at lower temperatures (16 minutes at 50° C; 30 minutes at 48° C). Chilling immediately in a refrigerator or even in cold water after the treatment will provide a reasonable degree of crispness in lettuce for prompt serving. The use of acetic acid or vinegar on fresh vegetables may destroy some cysts but under conditions of ordinary table use will offer little protection. To concentrate such attention on leafy vegetables may neglect the fact that cooked foods prepared some time before being eaten may have a good opportunity to become contaminated where the sanitary level is such as to permit gross contamination of leafy vegetables.

Heat is also, in general, the most satisfactory method of rendering water of unknown purity free of viable cysts. Water brought to above 50° C and held for at least a minute will suffice; if a thermometer is not available, bringing the water to the boiling point will be more than sufficient.

For chemical sterilization of water under emergency field conditions, iodine offers advantages over chlorine. Its action is less affected by pH, temperature, and even the organic matter present. A recently developed compound for this purpose is tetraglycine hydroiodide (globaline) \* which is less unpalatable than the chlorine or other iodine preparations. One tablet shaken up in a canteen of reasonably clear water will usually kill cysts within 15 minutes; with highly colored waters two tablets should be used.

There is no therapeutic or other chemical agent with a demonstrated prophylactic value. Fifteen years ago Craig concluded that diodoquin would effectively serve the purpose and urged that its possible prophylactic value be evaluated by extensive field trial. He suggested that seven tablets (0.21 gm. each) be administered for 20 days and, if exposure continued, be repeated after one week's rest. So far there has been no demonstration that such a regime would be either effective or safe. However, the South Bend epidemic showed that mass treatment with either fumagillin or oxytetracycline will eliminate the infection from such a community. Nevertheless, neither is recommended for prophylactic use during continued exposure to infection.

**Treatment.** Of the therapeutic agents which have been extensively used, only emetine offers prompt relief of colonic amebiasis. Emetine is, however, not curative and must be followed by one of the arsenicals, such as carbarsone or one of the iodinated oxyquinolines, such as chiniofon (yatren, anayodin), diodoquin or vioform. One of the newer antimalarials, chloroquin has been shown by Conan and others (1950) to be effective in amebic hepatitis. Among the newer drugs which seem to offer considerable promise are such synthetic organic chemicals as milbimide and manatomide and such antibiotics as oxytetracycline, fumagillin and erythromycin.

\* There has been considerable misunderstanding on the chemistry of this material; in earlier literature it has been referred to as triglycine hydroiodide and triglycine hydroperiodide.

erson and others, 1954; McHardy and Frye, 1954). There is considerable difference of opinion as to their precise value in relationship to each other and to older organic compounds.

#### INFECTIONS WITH OTHER AMEBAE

Of the other species of amebae which have been reported from man, the question of possible pathogenic role can be seriously raised only for *Dientamoeba fragilis*. This small binucleate parasite is not readily seen in routine fecal examinations, and even smaller uninculeate stages are usually missed altogether. It is probable that infection is more common than generally revealed by routine surveys. Since the development of a supravital stain it has been found fairly commonly in a small series of examinations, and in 1937, Wenrich, Stabler, and Arnett reported 4.3 per cent among over 1,000 students in Philadelphia. Usually, no clinical manifestations or history of such manifestations are associated with the presence of these organisms. The increasing number with recurrent episodes of abdominal distress and bouts of accompanying diarrhea suggests that this organism should be kept under suspicion. Hakansson (1937) has included burning sensations on defecation as one of the characteristic manifestations. Treatment with carbarsone as for *Entamoeba histolytica* is said to alleviate the symptoms and remove the organisms. Since cysts of this organism are unknown, it is generally assumed that infection results from ingestion of the trophozoites. Little is known of the epidemiology except that in an insane asylum Hakansson found 16 new infections in 38 patients within a year after successful treatment for *E. histolytica*. It is assumed, then, that it is a fecal-borne disease as the other amebic diseases, and flourishes where encouraged by unsanitary habits of fecal disposal. No specific control measures can be recommended.

*Entamoeba coli*, *Endalimax nana*, and *Iodamoeba williamsi* \* (= *I. butchlii*) may be dismissed as harmless commensals. They are of concern only to the extent that their presence in the feces may be a source of confusion in the attempt to determine by microscopic examination whether or not *E. histolytica* is present. For instance, to assume that any active trophic ameba in a dysenteric, diarrheic, or bloody stool is *E. histolytica* is to disregard the fact that the same stage of any of the above amebae will occur in such stools if the patient harbors the organisms. *Entamoeba gingivalis* is a nonpathogen of the mouth which occurs only in the trophic stage. No cysts are known. Since these amebae do not ordinarily survive passage through the stomach they do not even offer sources of complication in the microscopic examination of feces; transmission of this form is by kissing.

#### BALANTIDIASIS

*Balantidium coli* normally occurs in swine but is also found in the guinea pig and the chimpanzee. Its presence in these animals is not associated with any pathology, but in the colon of man flask-shaped ulcers not unlike those of amebiasis are produced, and chronic or recurring diarrhea or dysentery results. Fortunately, infection in man is comparatively uncommon but the several hundred cases which have been reported are widely scattered over the world. It is most commonly found in those with conspicuously close association with hogs, such as swine herders and gut strip-

\* Derrick (1948, Tr. Roy. Soc. Trop. Med. & Hyg., 46:41-42) reports the finding of an organism indistinguishable from *I. williamsi* in the alimentary canal and other tissues, including the nervous system, in a postmortem examination in the Pacific.

pers in abattoirs. Most human infections, therefore, appear to have resulted from the ingestion of the cysts of these ciliates of porcine origin. However, Young (1937) found 5 per cent infection in patients in a mental institution removed from any immediate porcine contact but living under grossly unsanitary conditions of their own making. The introduction of a single infected individual into such an environment provides excellent opportunity for transmission and does not contradict the premise that most infections have an immediate porcine source. As with amebiasis, control under such conditions is unremitting sanitary disposal of feces. The transmission from pigs to man is, perhaps, more subtle but should be readily interrupted among such handlers by washing the hands and preferably also changing clothes before eating or otherwise bringing the hands to the mouth. Treatment is with carbarsone, as in amebiasis, and is successful according to Young and Burrow (1943).

### FLAGELLATES AND FLAGELLATE DIARRHEA

It is doubtful that any of the intestinal flagellates produce diarrhea with an degree of regularity. Certainly, *Trichomonas hominis* and the small flagellate *Embadomonas* (*Retortomonas*) *intestinalis* and *Enteromonas* (*Tricercomonas*) *hominis* may be completely discounted. Recurrent diarrhea has been reported associated with *Chilomastix mesnili* infections but the diarrhea appears to develop often after the demonstration of the organisms as before such demonstration. There is more suspicion that *Giardia lamblia* may produce diarrhea. Diarrhea, epigastric pains, nausea, and migraine-like headaches developed in one accidental laboratory infection of an adult and terminated upon chemotherapeutic removal of the organisms. In Europe, celiac syndrome in children has been associated with the presence of these organisms but they may have been only a source of confusion or at most a complication. The infection is most common in children in the first decade and this age group prevalence rates as high as 30 per cent have been reported without any indication that the organisms were more than harmless commensals. Perhaps in the initiation of the infection or with particularly rapid multiplication they may be troublesome. Prevention is essentially as in amebiasis.

Although not an intestinal form, *Trichomonas vaginalis* may be mentioned briefly here. The infection is transmitted primarily by coitus but infection of female baby may take place at birth; such infections appear to be of short duration (Trussell, 1947). Infection rates of 10 to 70 per cent have been reported in adult women in the United States and Europe. In general, the infection rate in Negro women is about twice that in white women of the same age groups in the United States. Within each race the infection rate is highest in the 20 to 40 age group. The infection seems to be somewhat more common in pregnant than nonpregnant women. Few adequate surveys have been made of males but recent surveys have revealed that it is much more common than formerly supposed. As with women, Negroes appear to be much more frequently infected than whites; Roth reported 25 per cent in the former and 4 per cent in the latter and Feo found 17 and 12 per cent, respectively, in the two races. There is no demonstrated pathology or symptomatology in the male and most females harbor the infection without manifest difficulties. However, both in natural and experimental infections a small portion of the women, particularly pregnant women or nonpregnant women immediately after menses, v

er extensive inflammation of the vaginal mucosa with a characteristic frothy discharge. Prevention is similar to that in other venereal infections but complicated by the fact that most of the infections in women and apparently all the infections in men are asymptomatic and hence not usually detected. Treatment is not wholly satisfactory but the best results have been obtained from adjusting the pH of the vaginal tract. The organisms in culture grow best at pH 5.5 to 6.0 and the heavily infected tract has the same pH range. In culture or in the vagina, growth apparently never takes place below pH 5.0 or above pH 7.5. Thus, acidification or further alkalization of the tract appears to be beneficial but, since the normal pH is 4.0 to 5.0, acidification is more readily induced and the beneficial results are more quickly obtained and relapse appears to be less likely.

## ANCYLOSTOMIASIS

Recently, Stoll estimated that 457 million people or nearly a quarter of the world's population are infected with hookworm. However, not all the infected individuals show evidence of disease, and in some areas, the portion of the infected populace who suffer demonstrable ill-effects is relatively small. The chronic anemia and debilitation usually associated with the infection is not produced by hookworm alone. Malnutrition is invariably a factor which permits continued infection and reinfection (Cort and Otto, 1940). Long standing "hookworm disease" is then the product of malnutrition and continued blood sucking of the worms. Both laboratory studies and field observations suggest that it is impossible for chronic debilitating hookworm disease to develop in the otherwise healthy individual. Uncomplicated hookworm disease is rarely seen. It occurs only as an acute hemorrhagic disease produced by a large number of worms acquired at one time or in rapid succession over a short period of time.

Historically, hookworm is significant since it was this disease which challenged the organization of the Rockefeller Sanitary Commission out of which grew the International Health Division of The Rockefeller Foundation. This disease was also the direct stimulus for organizing many rural health departments in southern United States and abroad.

**Adult Worms.** The two species of hookworm of man are the Old World hookworm or European hookworm, *Ancylostoma duodenale* and the so-called American hookworm, *Necator americanus*. The former is the more pathogenic and the larger of the two (males 8-11 mm.; females 10-15 mm.) and armed with cutting teeth in the mouth parts; the latter is smaller (males 7-9 mm.; females 9-12 mm.) and has less effective cutting plates in the mouth. There is also some evidence that the former is more resistant than the latter to chemotherapy. Both species are confined to man. The common hookworm, *Ancylostoma caninum*, of dogs does not infect man. However, much of our knowledge of hookworm disease has been gained through the experimental study of this species in its normal host. Another hookworm, *Ancylostoma braziliense*, of dogs and cats in the tropics will penetrate the skin of man but does not normally complete its development in that host. It may migrate in the hypodermis for weeks or even months before it dies and thus produces the condition known as creeping eruption.

**Life Cycle and Method of Infection.** The adult worms live in the small intestine, where both the males and females remain attached to the mucosa and suck blood. Laying appears to be an almost continuous process. The eggs are in the early cleavage stages (2 to 16 cells) when passed in the feces. These mature and hatch within 24 hours. The first stage or rhabditiform larva feeds on bacteria, grows, and moults into the second or transitional stage which in turn feeds, grows, and moults to the third stage or filariform larva; this is the infective larva. Under optimum conditions the infective larvae appear within a week after eggs are laid, but at sub-optimum temperatures may require 10 days to two weeks. The infective larvae do not feed but may survive for weeks or even more than a month under suitable circumstances. They do not migrate laterally but will migrate vertically to reach the surface. However, effective vertical migration is limited to moist soils with a moist surface. In a moist, sandy soil a few may migrate vertically to reach the surface but even under these conditions less than half of them will reach the surface alive from a depth of more than a foot. With clay soils or dry soils vertical migration is further reduced.

Infection normally takes place by the active penetration of the larvae through the hair follicles or abrasions of the skin; they can also penetrate the mucous membrane of the mouth and apparently they may become established when swallowed. The larvae do not migrate directly from the skin to the intestine but enter the venous circulation and are carried to the lungs where they break into the alveoli, ascend the trachea, and are swallowed to reach the intestine. Growth and maturation in the parasitic phase involve two additional moults and require over a month. The first eggs appear in the feces about six weeks after the larvae penetrate the skin.

It is evident that a few adult worms may live in the intestine for more than five years and perhaps as long as 10 years. A number of lightly infected individuals living under conditions which appear to preclude the chance of reinfection have continued to pass eggs in the feces for well over seven years. It is equally evident, however, that most of the adult worms survive for only a short period of time. The rate of loss is largely a function of the immunological status of the host as will be noted later. It is possible to generalize, however, to the extent of saying that most of the worms are lost in less than six months.

Egg production of the worms is also influenced by a number of factors such as age and number of worms, nutrition and interrelated immunological status of the host. On the average, however, the female of *N. americanus* lays about 8,000 to 10,000 eggs per day and *A. duodenale* about twice as many. Fecal examinations for hookworm eggs are an invaluable procedure both to the clinician and the epidemiologist. Effective use of the technic requires an appreciation of the quantitative aspects of the infection. In the clinical laboratory, the simple saline smear is completely inadequate. It is true that some very light infections will be missed but it is hardly conceivable that any infection heavy enough to produce clinical manifestations will be missed; in fact, a great many subclinical infections will be discovered. Accordingly, except for special studies, concentration techniques such as by brine flotation or by zinc sulphate flotation, while suitable, are unnecessary.

For epidemiological studies it is desirable to use some quantitative measure of infection. For this purpose the Stoll dilution egg counting method has had the widest use and has the virtue of being simple. Recently, Beaver has reported the use of the

photo-electric measurement to standardize the saline smear and, by counting the eggs in this standardized smear, has obtained a quantitative measure of the infection. For years the Georgia State Health Department has obtained some quantitative measure of the infection by the use of a quantitative brine flotation. A standard amount of feces is used (1 gm.) and the quantity of eggs recovered are roughly classified as 1, 2, 3, and 4 plus. Any of these quantitative technics may be employed but the Stoll dilution egg count has had the most extensive use in critical epidemiological studies. A reasonable estimate of the number of *N. americanus* present may be obtained by dividing the number of eggs per gram of feces by 25. The variations are such, however, that any attempt to determine the number of worms in a given individual from a single stool examination will be subject to large errors.

**The Disease.** Chronic or recurring hookworm disease is characterized by continuous or recurring hypochromic microcytic anemia. As already noted this condition results from the bloodsucking activity of the worms and a predisposing malnutrition. It is remarkable how a severely infected individual can survive but deaths are not common. Rather there is produced a state of chronic debility. The anemia may result in a compensatory enlargement of the heart and children may be mentally, physiologically, and physically retarded in their development. In the individual sensitized by repeated infections, "ground itch" due to the penetrating larvae may be severe.

Severe outbreaks of acute hookworm disease have been described. Ashford and others (1933) reported one such outbreak involving a whole family of good nutritional status which had received an unusually heavy exposure to infection. The provisional diagnosis was established early, before eggs appeared in the feces, on the basis of the extensive but mild ground itch, followed by pulmonary symptoms and the development of severe anemia within three weeks accompanied by black tar-like stools and a marked eosinophilia (up to 80 per cent). Diagnosis was confirmed by treatment which removed thousands of immature worms and initiated rapid recovery. Such outbreaks are rare, but hookworm disease should be considered when transients, such as military personnel, in the tropics or subtropics are found to have a rapidly developing anemia due to blood loss through the intestine.

**Geographical Distribution.** Both of the species of hookworm of man have become widely scattered.

Although *N. americanus* was first described from the United States and thus commonly referred to as the American or New World hookworm, it appears to have originated in tropical Africa or southern Asia from which it has spread widely. Certainly it was brought to the Western Hemisphere from Africa in the Negro slaves. It now extends from the southern United States through the American tropics to the temperate zone of South America. It is the only common hookworm of man in this hemisphere and in most areas is present to the complete exclusion of the Old World hookworm. In Africa, it is largely confined to Central and South Africa with its most northern extension along the west coast to about 15° N. In southern Asia, it is the exclusive or dominant species but overlaps with the European hookworm in central India and central China. Similarly, it is the dominant species in the Western Pacific Islands, including Okinawa, Formosa, the Philippines, Java, Sumatra, the Celebes, New Guinea, North Eastern Australia, and Fiji.

4. *duodenale* may be classified as the temperate zone hookworm. It is the hookworm of the agricultural regions of the Mediterranean area, North Africa, Asia and Europe. Farther north in Europe it is found principally in the mines. As in the mining-like operations in the construction of the St. Gothard tunnel a severe epidemic developed in 1879 and provided the first indication of the significance of hookworm as a disease-producing organism. It is still a problem in some of the mines of central Europe, and was once a source of concern in the mines of England and Wales. Similarly, the introduction of this species into the gold mines of California by European miners created a serious problem which was brought under control over a quarter of a century ago. This species had undoubtedly been brought to this hemisphere in a great many immigrants from Europe but it has developed only into a few local foci in the rural areas of South America. Interestingly enough, it is found in a few of the native Indian tribes in South America who had little if any contact with Europeans.

This species is most prevalent in Central Asia. It is the exclusive species in northern India, north and central China and overlaps with *N. americanus* in central China and in central and south China. It is the dominant or exclusive species in Japan and the central Pacific Islands. It appears to be the exclusive species in the outback of western Australia.

It must be recognized that these generalizations on the geographical distribution of the two species rest on a limited amount of data. It is not possible to distinguish the species by examination of the eggs. Hence precise information on the geographical distribution can come only from observations on post-treatment or post-mortem examination of the adult worms. However, the epidemiological factors governing the distribution of both species are similar and may be discussed together. Furthermore, infection is not uniformly distributed throughout the broad geographical areas indicated. There may be little disease even where the infection is common, while in another area, without a materially higher percentage of infection, hookworm disease may be a serious problem. In the United States, the infection is largely confined to the southeastern part of the country and manifest disease is found only on the sandy coastal plains and a limited number of sandy valleys or plateaus in the adjacent mountain areas. Figure 3-8 (Hill and Andrews, 1942) shows the variations in the density of hookworm in a population correlated with hemoglobin concentrations. These observations were made in south Georgia where 40 to 50 per cent of the rural population are positive for hookworms. Of the 1,141 positive individuals under observation, less than 30 per cent were passing 8,000 or more eggs per gram of feces and had a measurable deficiency in hemoglobin. It is estimated that 8,000 eggs per gram indicates the presence of more than 300 worms. Thus, it may be said that somewhere near 10 to 15 per cent of the population from which this sample was drawn suffer demonstrable injury from the hookworms.

The various interrelated factors in the development and maintenance of hookworm infection and hookworm disease can be summarized under three broad headings: environment, human habits, and intrinsic host factors. The latter may be conveniently subdivided under race, immunity, and nutrition or malnutrition.

**Environment.** The free-living stage of the hookworms develops and survives in a moist, shaded, and warm environment. Temperatures of 75° to 85° F appear to be optimum but development is not materially retarded by occasional temperatures as

low as 70° F. Below 70° F development is retarded and is never completed at temperatures as low as 45° F. Above 85° F development may appear to be temporarily accelerated but may never be completed at high temperatures. A loose, sandy soil, with or without a high humus content, provides a good culture medium. Rocky soils or those containing a high clay content are unsatisfactory for the development stages. Laughlin and Stoll (1947) have shown that development readily takes place on bed clothing or wearing apparel which remain damp. Such clothing appears to offer optimum culture conditions since large numbers of larvae were demonstrated in the absence of visible contamination.

From Andrews, J., Am. J. Pub. Health, 32, 1942, Fig. 3.

Fig. 3-8. Average hookworm egg counts and hemoglobins, by egg-count classes, in 1,140 residents of South Georgia (curve fitted by inspection).

Drying is rapidly fatal to the larval stages and even the eggs will not survive long without moisture. Winds and sun contribute to the drying and the latter adds the lethal effect of heat. Thus, for the most part, only shaded soils offer the opportunity for development. When the surface of the soil is dry, some of the larvae may remain in the moist subsurface and emerge as rains or heavy dews provide sufficient moisture. However, there does not seem to be any tendency to burrow downward to moisture, and many are caught on the dry surface where they perish. Thus, rainfall or irrigation is important in providing adequate conditions for development. In general, even with widespread fecal contamination of the soil, relatively little hookworm disease develops when there is less than 40 inches of rainfall per year. In southern Georgia with about 50 inches of rainfall a year most of the transmission appears to take place during the limited periods of the spring or early summer and

in the early fall when repeated rains maintain a moist surface. During the summer when rains are less frequent and during the cooler winter months little or no transmission takes place.

Although the eggs and larvae require moisture, standing water does not provide suitable conditions for development, largely due to the low amount of oxygen at the bottom. However, temporary rain pools may provide points of concentration by drawing both eggs and larvae into these low spots.

**Human Habits.** Hookworm infection is sharply correlated with those human habits which concentrate feces in moist shaded places which are repeatedly visited. Only nominal attention to proper fecal disposal may be sufficient to prevent the spread of the infection. Even the unsightly and malodorous open-back privy, if persistently used, concentrates fecal material so that there is less chance of exposure. In the absence of any privy or in disregard of its presence, as in the poorer sections of the southern United States and in tropical America, fecal concentration is seen in secluded shaded areas near the house and continuous return to the same area provides a constant source of reinfection. Among the more careless elements of the population the feces, particularly of children, are often concentrated in the immediate proximity of the house (Otto and others, 1931). Under such conditions the family is the unit of infection and families in which all or most of the members suffer severely from hookworm disease may be found living close to other families with relatively little infection. Defecation in fields of growing crops is more diffuse and may help spread the infection but does not provide the concentrated sources required to produce severe disease, except under special circumstances. About the old one-room rural school houses, with inadequate toilet facilities, or none at all, fecal contamination was concentrated in the adjacent woods, by the girls on one side and boys on the other. The development of the consolidated rural school has tended to reduce this community source of infection. Chandler reports similar household and village fecal contamination in India. Scott and others (1934) found fecal concentrations between houses in the villages in Palestine. In Egypt, where there is relatively little wild vegetation and no habit of seeking concealment, defecation takes place in the street, yard, and fields indiscriminately (Scott, 1937). Soil contamination is widely distributed and the arid winds destroy much of the potential infection quickly. Thus, while hookworm is widespread in Egypt, the infections are very light and hookworm disease is rare.

Hookworm disease is directly or indirectly an occupational hazard in a number of ways. Mention has already been made of the disease in the miners in Europe and California. Transmission under these circumstances is exclusively, or almost exclusively, a result of uncontrolled defecation in the mine passages. There, constant moisture and an even temperature provide for the maximum life of the worms with ample opportunity for infection. The exposure is largely suffered by the adult males who work in the mines. The brick-maker's anemia of Italy and Germany in the past century was the result of a similar concentration of hookworm infection where the men worked. In this connection mention should be made of the infection of laundry sorters who became infected at the Navy laundry on Guam as a result of sorting soiled clothing which had been allowed to accumulate a week or more in a damp place before being laundered.

The best examples of the occupational relationship to infection among agricul-

tural workers are in silkworm and sweet potato cultivation in China. In the Yangtze Delta and in Kwangtung Province mulberry trees are grown for the sole purpose of providing leaves for silkworm cultivation. After the spring crop of leaves is picked the ground is cultivated and trees fertilized with a liberal application of night soil to force the next crop of leaves. The night soil used is both that which has been stored for some weeks or longer, in which most of the hookworm eggs have died, and the fresh night soil from the local population which contains viable hookworm eggs. Thus, the moist, shaded areas under the small trees are teeming with infective larvae when the next crop of leaves are picked. Cort reports as many as 10,000 infective hookworm larvae from a single soil specimen taken from the base of a mulberry tree at the time of the second picking of leaves. Ground itch annually occurs among the mulberry pickers at this time, and is followed by a cough (from the migrating larvae), and later by anemia. There must be a considerable loss of worms in the intervening year since with many individuals this sequence of events is an annual occurrence. All elements of the population are involved but since the picking of the mulberry leaves is primarily assigned to the women they are the ones who suffer most. However, in Szechwan Province the extensive mulberry raising is not associated with the spread of hookworm disease due to differences in practice. In this northern province the leaves are only picked once, in the spring, and trees are fertilized with night soil after the picking. Eggs and larvae could not survive until the next season. Furthermore, the trees in this area are allowed to grow tall so that leaves are picked from ladders which reduces contact with the soil and thus reduces the opportunity for infection even if the night soil were applied before the leaves were picked.

The sequence of events in the cultivation of sweet potatoes in Szechwan Province, however, provides opportunity for massive infections. Corn is planted and fertilized with night soil and weeks later, when the infective hookworm larvae are abundant, sweet potatoes are planted by hand thus permitting infection both through the hands and feet. In Fukien Province sweet potatoes are fertilized when planted and at least twice thereafter. The sweet potato runners are loosened by hand 15 to 20 days after each fertilization, when the infective larvae are abundant (Tang, 1949).

Although night soil is used to fertilize other crops, working is less consistently timed with fertilization by night soil. Furthermore, some crops, such as cotton, are grown on drier soil. Accordingly, hookworm disease is less prevalent in most agricultural workers than is the case with the silkworm culturists and the sweet potato gardeners. Rice cultivation actually offers protection from hookworm infection. The eggs do not develop in the night soil poured around the submerged rice plants and die in the water.

Both in the coffee groves of Puerto Rico and the orange groves of Palestine, promiscuous defecation among the trees provides scattered sources of later infection for the coffee and orange pickers but not the concentrated sources provided for the silkworm culturist and sweet potato gardeners of China.

**Intrinsic Host Factors. IMMUNITY.** Experimental studies have shown that dogs are capable of and do develop a highly protective immunity to *Ancylostoma caninum* (Oto, 1948), the normal hookworm of dogs. If a few larvae (15) are administered at weekly intervals for a month, and thereafter the dose is increased at weekly intervals, only a few worms—usually less than 200—will develop and survive and the animal will remain healthy and free of signs of hookworm disease.

though the final dose of larvae three to six months later is as high as 200,000. Mates receiving only the final dose of 200,000 invariably die within two weeks in blood loss and 10,000 to 50,000 worms are recovered at necropsy. When, however, the process is accelerated either by more frequent administration of the larvae or by more rapidly increasing the doses many worms become established and there is a rapidly developing anemia. A crisis is reached in a relatively short time either the animals succumb shortly thereafter or else the worms are discharged and the animals rapidly improve in health, *even though more infective larvae are continuously administered*. Such animals have been shown to be thereafter refractory to as many as a million larvae administered at one time. Quantitative aspects of this immune phenomenon have been clearly demonstrated. Puppies receiving a single dose of 300 to 600 larvae appear to be immune after two months to challenge doses of 10,000 larvae but are not immune to, and may be killed by, challenge doses of 100,000. However, initial doses of 1,200 to 1,400 larvae will render a puppy immune to 50,000 larvae. The serum of immunized dogs contains antibodies which form precipitates with the secretions and excretions of the infective larvae in vitro block the oral opening, and often the excretory pore as well. In the tissues of the immune animal the migrating larvae are retarded, apparently as a result of this precipitin reaction and thereafter are destroyed in the tissue reaction. Most of them appear to be arrested in the skin. Very few complete the migration to the intestine, and most of the latter fail to become established.

It seems probable that the phenomenon in man is similar. Only one experimental study with one human volunteer has been carried far enough to offer data on the subject. This individual received slowly increasing doses of larvae, a total of 5,000, over a two-year period following which a challenge dose of an additional 5,000 larvae was given. At no point in the study did the individual show any diminution of hemoglobin or loss of weight; in fact, there was a slight gain. Effective treatment and complete recovery of the worms revealed only 300 worms resulting from the total of 10,000 larvae.

It will be noted that in the one human subject and even in the hyperimmunized dogs some worms survived the immune process so that, insofar as the worms are a measure of immunity, it cannot be classified as absolute. If, however, immunity is measured, as it is in bacterial or virus infections, in terms of disease, then the immunity to hookworm is absolute. The first attacking larvae protected the host efficiently from subsequent attacks of larvae to prevent either a relapse of the disease or the development of a new attack. If immunity to hookworm were as effective in nature as it was in these experimental studies, chronic hookworm disease would never develop and only acute hookworm disease would be of concern. Obviously, there is some discrepancy between the experimental studies and the field observations, since hookworm disease is a chronic debilitating type of disease in many parts of the world, and with a considerable number of people it is a problem through much of their life.

**Intrinsic Host Factors.** NUTRITION AND MALNUTRITION. Wherever hookworm is common the chronic debilitating type of infection is seen in the lower economic groups of the population. The most superficial inquiry is sufficient to reveal the fact that such people do not receive a balanced diet and often the caloric intake is inadequate. The most conspicuous lack is usually animal protein, but the vitamins

are frequently lacking also. Obvious specific deficiency states may be recognized but more often they are not evident. Rather the nutritional condition may be considered as being marginal.

Experimental studies with a number of worm infections in a variety of hosts, but particularly those with *A. caninum* in the dog and the closely related *Nippostrongylus muris* in rats, have revealed that the nutritional status of the host has a powerful influence on ability to combat the infection. In many cases a much larger percentage of worms from an initial infection will become established in the malnourished host than in the control receiving a balanced diet. The differences, however, are less conspicuous and less consistent than those associated with exposure to subsequent infections. Foster and Cort found that dogs on a protein- and vitamin-deficient diet failed to develop the degree of immunity, as a result of repeated exposure to infection, which their litter mates on balanced diets developed. Furthermore, animals which were immunized while on a balanced diet became susceptible to infection when fed the deficient diet and *lost the infection again when* returned to the balanced diet. Donaldson and Otto (1946) later showed a similar relation of protein in the diet to immunity in rats exposed to *N. muris*.

A quarter of a century ago Fülleborn found that in the cattle raising areas of the Argentine where nutritional conditions were good there was very little hookworm disease. The lack of sanitation on a sandy type of soil and in a warm climate seemed to offer a favorable environment for transmission; a 40 per cent infection rate demonstrated that transmission took place. Fülleborn, at that time even before the experimental demonstration of the immune phenomenon in this infection, suggested that immunity played a part in the protection of these well-nourished Argentinians. Among the populations of the world who maintain hookworm infection by their defecation habits in a suitable environment for transmission, there is every gradient in the nutritional status from that of Fülleborn's Argentinians to the completely undernourished conditions seen in some of the poorest hookworm families of the southern United States, in China, and elsewhere. Thus, there are various levels of immunity affected by nutrition. The limited number of observations which have been made on the temporary improvement of the diet of malnourished hookworm patients have shown that some amelioration of the anemia may result and worms may be lost without specific chemotherapy.

The observations of Cruz in Brazil also emphasize the nutritional factor in hookworm disease. Since the hematopoietic system appears to suffer little or no irreversible damage he finds that the addition of iron to the diet will stimulate hematopoiesis and the anemia can be corrected without the removal of the worms. Where the iron deficiency is a conspicuous part of the picture and the limited iron resources are further depleted by the blood sucking activities of the hookworms the specific addition of iron is significant. However, dogs infected with hookworms while receiving diet deficient both in iron and protein, as well as vitamins, showed only a transient hematopoietic response to the administration of iron (Otto and Landsborg, 1940). Under these circumstances continued administration of iron did not affect the ultimate fate of the dog or the worms. Similarly, Payne and Payne (1940), working with a population in Puerto Rico whose diet was deficient in protein as well as iron, found that supplementary iron was beneficial for only a few months; thereafter, anemia again developed despite the continued use of iron. The reason is

ent when one considers that iron is but a small portion of the hemoglobin molecule. Protein and other dietary constituents appear to be required for the formation of hemoglobin as well as for the development of immunity.

**Intrinsic Host Factors. RACE.** The Negro is much less susceptible to hookworm, at least to *N. americanus*, than any of the other human races. In Africa, there may be a high infection rate with relatively little disease but in the United States Negroes living under the same sanitary conditions as the whites will usually show no evidence of hookworm disease and a much lower percentage of infection than the latter. The reasons for this are not at all clear. Various explanations have been offered, all of which are postulates, and any of which may have at least some significance. Since *N. americanus* appeared early in Africa it is probable that there has been some natural biological selection over the centuries. It has also been postulated that the hookworm may find it more difficult and often impossible to penetrate the thicker skin of the Negro. However, racial differences in susceptibility to other worm infections are known to occur with a number of species of animals in which skin penetration is a factor. Thus, at the present state of our knowledge it is not necessary to invoke a difference in skin thickness to explain the difference in racial susceptibility; there is no precise support for the postulate, but it cannot be completely disregarded on that account. In the southern United States, at least, there is another very consistent difference between the rural Negro and his economic counterpart, the poor white sharecropper. The latter families, whether they harbor hookworm or not, frequently have thin, underweight, and may look emaciated. The Negro children and young adults, at least, have a well-fed look about them and are generally heavier. To what degree this difference is genetic and how much it reflects a difference in the utilization of the limited resources and opportunities to get food is not clear. Furthermore, whatever role this plays in the relative susceptibility of the two races to hookworm is not known. In short, the underlying mechanism of the difference in racial susceptibility or immunity is not known but warrants careful investigation.

**Prevention of Hookworm Disease.** The prevention of hookworm disease is most logically considered with reference to that portion of the population whose sanitary habits are such that they do not maintain their own sources of infection. This would include transient, semipermanent, and permanent populations, both civilian and military, living in the endemic area.

It is necessary only to prevent contact with infested soil. This is almost completely accomplished by wearing shoes, and for the most part no other admonition is needed. A few special points may be mentioned in addition. Children, particularly young children, should be prevented from wandering into unsanitary areas where by playing on the ground various parts of the body may come in contact with the infested soil. Temporary rain pools or pools replenished by heavy rains should be avoided for wading or swimming if they receive washings from privies or slopes on which defecation commonly takes place. Sea water, however, does not constitute a hookworm hazard. Military personnel on training or combat maneuvers may find it difficult to avoid contact with infested soil. Clothing, such as uniforms, which will amply protect against the infective larvae under most circumstances, and the handling with bare arms and hands of the unwashed bed clothing or personal wearing apparel of infected individuals should be avoided if such clothing is stored more than five days, particularly when it is damp and warm.

**Control of Hookworm Disease.** Theoretically, it should be possible to control hookworm disease in the indigenous population within an endemic area by the simple expedient of providing privies or shoes for everyone. The difficulty results from the fact that the severe form of hookworm disease is found only among the economically unfortunate group of the population. Living as they do on a marginal basis, only the bare necessities of life are provided, and in the absence of climate pressure for protection, privies and shoes are of minor concern or scarcely even considered. Against this economic background sociological habits have developed. Shoes, when provided, may be worn as a matter of pride on occasion but not for comfort or as protection. When a privy is provided through official or private means, even when built by the members of the family, it is indifferently used. The "privy habit" does not develop easily against such a social and economic background.

The problems are equally complex where night soil has an economic value as fertilizer and agricultural habits are intrenched.

Nevertheless, some progress has been made in the slow process of education. The several approaches and results may best be considered under a series of sub-headings.

**MASS THERAPY.** The earlier attacks upon the hookworm problem centered around treatment. Two basic approaches were used: (1) the treatment of all those found positive on routine fecal examination, or (2) treatment of all personnel, regardless of the individual infection status, when a preliminary survey revealed that the infection was common. In many respects this is the easiest official approach to the problem since it requires the minimum cooperative effort on the part of the individual. However, at best, treatment alone does little more than put a worm-free episode into the life of the infected individual. It requires periodic repetition. In both the individual and the community the pretreatment level of infection is quickly restored. Sawyer showed the return of the hookworm population follows the same trends and ecological experiences as free-living populations. The more effective the treatment, the more rapid is the immediate rate of reinfection, and complete reinfection to the pretreatment level may take very little longer than with less effective treatment. It may take no more than three to five years to completely nullify the effects of treatment in a community. Treatment alone, even with continued repetition, has not been successful in the control of the disease. It has, however, proved to be a valuable introductory and supporting measure; it is a means of gaining the confidence and cooperation of the populace and at the same time gives the treated individual a temporary period of improved health. Treatment is then an important part of the control program. Tetrachlorethylene is the drug of choice, and the adult dose is 5 ml. preferably without any purgation (Carr and others, 1954).

**PRIVIES.** The basic issue is how best to interrupt transmission in a permanent manner. This interruption cannot be accomplished without the direct and active personal cooperation of the populace involved. The provision of sanitary facilities does not insure their use. Since the problem of providing sanitary facilities in the control of hookworm disease is basically in the poorer rural population, the privy is the only facility which can be seriously considered. It is desirable to enlist the active participation of the individuals in the construction of the privies. Hence they should be simple. They should preferably be such that the infected families can provide

within the limits of their resources (see material on sewage disposal, page 42).

Stress is put upon the privy at the home because much of the hookworm, outside China, is transmitted in this environment. However, similar provisions should be made where agricultural workers will find them conveniently available in the field.

The provision of privies in mines has eliminated the problem in such cases. Apparently, however, there are still some mines which have not yet been adequately provided with these facilities.

**NIGHT SOIL.** The economy of much of China is geared to the use of night soil as fertilizer. Any attempt to completely eliminate the practice would create as many problems as it would solve. Fortunately, hookworm eggs and the eggs and cysts of most other intestinal parasites can be killed by the simple expedient of storing. In most areas the principle of storage is already used in both urban and rural areas. The object is to accumulate this fertilizer for application at particularly specified growth stages of the crop in question. Considerable success attended efforts in China before the war to bring about standardized storage practices. Many of the eggs are destroyed in less than a week but two to six weeks may be required to kill all of them in the summer under various types of storage. The addition of unslaked lime or ammonium sulphate will hasten the process but the addition of these or other killing agents appears to be economically impractical.

Chang (1949) has also found that simple shifts in the manner of the interplanting and fertilization of corn and sweet potatoes can materially reduce the exposure to infection among the agricultural workers tilling these plants.

**SHOES.** The wearing of shoes or any impervious covering for the feet will prevent the entrance of the larvae through these extremities. However, even when economically feasible it is difficult to keep shoes on children in the tropics or during the warm weather in the south. In the case of agricultural workers, in such crops as sweet potatoes, protection should be provided for the hands as well. Certainly the protection of the feet, as well as other parts of the body, should be encouraged but the limitations should be appreciated.

**EDUCATION.** The necessity for education to implement any control program cannot be too often emphasized. Such education can be accomplished through schools, in community meetings, and by the distribution of simple literature. The plans of the Georgia Health Department (Andrews, 1942) developed and put into operation before World War II, centered around the family unit. The hookworm families were discovered by routine surveys, commonly surveys in the schools, and some contacts made where children were found passing more than 5,000 eggs per gram of feces. An anthelmintic (tetrachlorethylene) and an iron supplement (Blaud's pills) were provided, and the underlying causes of the disease were discussed. Advice was offered on dietary improvement and stress was placed on sanitary disposal of feces. Assistance was offered in the construction of a simple but effective privy.

In the past 35 years, the amount of hookworm disease in the United States has been reduced. It is difficult to evaluate the specific factors involved but it seems evident that education has been a significant factor, and that recurrent treatment has had an educational value, at least, and that some economic improvement has helped in the improvement of sanitation both through private and public means.

The scope of the problem is constantly narrowing and concentration on the family unit is more and more indicated.

**PREVENTION AND CONTROL OF CREEPING ERUPTION.** Since this condition is caused by the penetration of the dog and cat hookworm, *Ancylostoma braziliense*, the disease may be prevented by not bringing the skin in contact with soil on which dogs and cats have defecated. This may be difficult to completely avoid in the case of children or with certain workmen, such as plumbers working under houses. Keeping dogs and cats from areas where children play is of very definite value. Attempts have been made in Florida, where the disease is common, to exclude dogs and cats from beaches. Treatment of household pets should prove to be of value.

### ASCARIASIS

The large roundworm, *Ascaris lumbricoides*, is widely distributed in the tropics and subtropics. It is probably the most common cause of worm infections of man in the tropics. Its distribution overlaps that of hookworm but often the areas in which it is most common are relatively free of hookworms. Although it is found in all age groups it is usually most common in children. In the United States it is most common in the eastern mountain areas from West Virginia southward (Otto and Cort, 1934).

**The Worm and its Life Cycle.** The adult worms (males 6 to 8 inches; females 9 to 15 inches long) live in the small intestine. They do not have any structures for attachment but feed upon the intestinal contents and hold themselves in position by lying U-shaped or even C-shaped and exerting a spring-like pressure against the intestinal wall. They are more prolific than the hookworms; the female lays about 200,000 eggs per day. The eggs are discharged in the feces in the one-cell stage and require not less than two weeks to become fully embryonated; it may take over a month for this process. They do not normally hatch until they are ingested. The newly hatched larvae are unable to develop in the intestine until they have completed a migration via the blood stream to the lungs, through alveoli and up the trachea to be reswallowed. About two months are required from the time the embryonated eggs are ingested until the worms have matured and eggs from them are discharged into the feces. The adult worms probably have a maximum life of less than a year and most of them are lost in less than six months.

**Pathology and Clinical Manifestations.** There is no well-defined clinical manifestation from which the presence of these worms may be suspected. The presence of the worms, therefore, can be routinely determined only by finding the eggs in the feces, either the normal one-celled eggs or unfertilized eggs; the latter will be found exclusively when solitary females have developed, or in other light infections. The worms may be seen with the fluoroscope following a barium meal. Since the eggs are so easily detected this has only limited clinical value and is of no significance in routine surveys.

The young worms undoubtedly damage the lungs during the pulmonary migration but unless there is massive invasion at one time there are no marked clinical manifestations. The adult worms may produce serious mechanical injury by perforations. Such damage appears to be most common when they are hyperactive due to fever, usually of some other origin, or due to chemical stimulation by ether or some other volatile anesthetic. Masses of the worms may produce blockage in the

all intestine or elsewhere in the alimentary tract. The only consistent systemic action is the development of an allergic reaction; commonly there is a history of old but recurring asthma (Keller and others, 1931).

**Transmission of the Infection.** *Ascaris* eggs are apparently the most resistant of the eggs and cysts of the parasitic worms and protozoa. Unfortunately, the tendency to cite the extreme survival time of the embryonated eggs has had misleading epidemiological implications. It is true that when *ascaris* eggs are maintained in water in the refrigerator a few will survive five years or more. However, even under these conditions most of them are dead within a much shorter period of time and when they are maintained at room temperature they scarcely survive a year in clean water. When oxygen tension is reduced chemically or biologically death is more rapid. They cannot develop at temperatures above  $37^{\circ}\text{C}$  and usually die in less than a week at this temperature; they are killed in less than an hour by temperatures above  $50^{\circ}\text{C}$ . They are quickly killed by sunlight or by desiccation. However, they will survive for months on the surface of soil if either subsurface moisture or a high atmosphere moisture, above 80 per cent relative humidity, is sufficient to prevent complete drying. Fecal plants on various types of soil in the endemic areas of Panama and the southern United States have shown that the eggs are destroyed in a few days in the sun but will survive for months in the shade.

Thus, the resistance of some of the eggs permits rather wide distribution in the endemic areas but heavy infections are maintained where there is close contact with soil on which there is continuous deposition of feces. Since there is no free-living larval stage, loose sandy soils are unnecessary, indeed may even permit the washing of eggs beneath the surface out of contact with man. Since the embryonated eggs must be ingested, defecation sites some distance from the house reduce the hazards of infection with these worms, whereas they may be the main source of infection with hookworms. It is dooryard pollution alone which permits continuous heavy infection (Brown, 1937). To a very appreciable degree the prevalence rate of *ascaris* may be taken as a direct index of the degree of insanitation. A high rate in children indicates that they play more or less continuously where they defecate. Casual eating or otherwise bringing contaminated hands to the mouth in such situations provides the optimum conditions for infection. In the United States, and much of the world, the family is the unit of infection with children playing the major role in transmission. Other units are mental hospitals and orphanages.

The use of night soil as fertilizer may help spread the infection where this practice exists but it is unlikely to build a heavy focus of infection alone. Even in China, where night soil is almost universally used for fertilizer, the *ascaris* infection is largely concentrated in those families with young children who regularly defecate in the dooryard.

**Prevention and Control.** As with any feces-borne disease, control is directed to the prevention of contamination of food or drink by feces. With this infection it is not fresh feces, but rather the eggs remaining and which have developed after most other evidences of feces have disappeared which are of concern. The general concepts of cleanliness in preparation and handling of food and drink and in consuming them need not be repeated.

The attack on the endemic source of the problem is through the slow process of education to bring about proper fecal disposal. Where night soil is used for fertilizer,

storage will destroy many eggs. Apparently most of them are destroyed in less than a month but under some conditions, particularly in cooler weather, they may survive for a longer time. Winfield (1934) has utilized ascaris eggs as an index of the effectiveness of storage methods; when ascaris eggs have died one may be sure that the eggs or cysts of the more severe pathogens, i.e., hookworms and *E. histolytica* have long since died.

Although the simple piperazine salts as well as hexylresorcinol are effective against ascaris, therapy has no demonstrated value as a public health measure (Otto, 1930).

### TRICHURIASIS

The whipworm, *Trichuris trichiura*, has a life cycle very similar to that of ascaris but differs in a number of details. It is a much smaller worm, it lives in the cecum, and the long whip-like anterior end is sewed superficially into the mucosa. There is no migration outside of the alimentary tract, the larvae, which hatch from embryonated eggs which have been ingested, apparently grow and undergo their several moults in the cecum. The adult worms live several years, apparently commonly as much as 5 to 10 years. They lay very few eggs per day compared to ascaris and hookworms; it is variously estimated from 1,000 to 3,000. The eggs are passed in the one-cell stage and require about a month to become embryonated. The eggs are much less resistant to drying than are the ascaris eggs so that the worms have a much more limited distribution. *Trichuris*, like ascaris, is common only when children or adults live, play, and eat on soil where fecal contamination takes place. However, *Trichuris* flourishes only where high ground water, heavy rains or some other source of water maintain a very moist soil (Spindler, 1929). It is particularly common in some mental hospitals. Outside of such institutions it is commonly found in southern Louisiana and to a more limited extent in the mountains of southeastern United States.

Their possible relationship to disease is not clearly established (Otto, 1935).

Prevention and control is essentially the same as for ascaris. No effective treatment is known.

### STRONGYLOIDIASIS

*Strongyloides stercoralis* is a small worm which lives partially burrowed superficially in the mucosa of the small intestine. Normally, the eggs laid by the female develop and hatch as they pass down the alimentary tract so that first-stage (rhabditiform) larvae are passed in the feces. Under suitable environmental conditions infective (filariaform) larvae develop in two to five days. All the free-living stages are quickly killed by drying, reduced oxygen tension, and by temperatures materially above or below the optimum which is 70° to 85° F (Cordi and Otto, 1934). The susceptibility of the free-living stages to adverse environmental conditions is in part balanced by a short period of free-living life and the fact that in the interposition a free-living sexual generation may permit multiplication during free-living life. Infection is commonly found, then, only in the tropics and subtropics where ground water or rainfall provide a moist soil. In the United States this infection appears to be common only in south central Louisiana but is found to a limited extent elsewhere in the southeastern part of the country. Although a high prevalence rate is found only in limited areas, the infection is widely scattered in a few people. Apparently

infection may persist for decades, once it becomes established. Each worm, however, lives for only a short time, apparently a matter of months and appears to lay only a few hundred eggs. These facts, together with the poor survival of the free-living stages, lends support to the belief that autoinfection is common. Whether this is a process of internal reinfection or external reinfection due to poor personal hygiene is not clear. Because the egg production is so low the resulting first-stage larvae may be very sparse in the feces and difficult to demonstrate even by repeated examination. Only freshly passed feces should be examined.

Prevention and control are as with other feces-borne diseases. Treatment may be required if a persistent infection is troublesome. Gentian violet is the drug of choice.

### ENTEROBIASIS

The pinworm or seat worm, *Enterobius (Oxyuris) vermicularis*, is the most widely distributed of the worms infecting man. In some areas of the tropics its prevalence rivals that of ascaris. In most areas in the temperate zone it is much more common than all other worms combined. It occurs in all age groups but it is by far most common in young children. Over 50 per cent infection was discovered among children in a private day nursery in Washington, D. C. (Cram and Nolan, 1939). The adult worms live in the lumen of the cecum; when the female is ripe, i.e., full of eggs, she migrates to the anus where the eggs are discharged either through the perianal pore or by complete rupture.

Accordingly, eggs are not mixed in the feces, as is the case with other worms which lay their eggs within the alimentary tract; routine fecal examination is essentially useless in attempting to establish the presence of the infection. Since the worms usually make their egg-laying migration after the subject retires, diagnosis, in children at least, is most easily established by direct examination of the anal area one or three hours after retiring. Eggs may be collected by scraping the area with the sticky surface of Scotch tape in the morning before there is any bowel movement. The Scotch tape should be immediately stuck smoothly to a glass slide, thus binding the eggs for subsequent microscopic examination.

Some of the eggs may be completely embryonated when laid, while others may require up to eight hours additional time for embryonation. The shells have a cement-like substance with which they become stuck to the mucous membrane, skin, hair, or clothes. Infection results from ingesting the embryonated eggs which hatch in the small intestine; the larval stages grow and undergo a series of moults, probably four, as they make their way to the cecum. The entire life cycle may be completed in less than a month so that reinfection alone accounts for the persisting infection in a given individual. Internal auto-reinfection has been invoked to explain persisting infections but there is no direct support for this postulate and it disregards the obvious opportunities for anus to mouth reinfection. The eggs apparently survive only a short period of time and while they have been recovered from dust in various rooms, even public school rooms, most of those so recovered are dead. This may represent one means of the dissemination of infection but much more intimate contact is required for rapid spread. Thus, it is common in orphanages and mental hospitals but passes equally as well within a family. It is no respecter of economic status or the usual concepts of personal cleanliness. Once a child in a family be-

comes infected, the infection spreads rapidly to other children and to any adult, as the mother, who is in close attendance upon the children. Not infrequently all members of the household become infected. It may be referred to primarily as an intramural infection. It is not clear whether changes in habits of personal hygiene or the development of an immunity keeps the infection rate down in adults; perhaps both are operative. The fact that the mother commonly becomes infected from her small children is suggestive. Prevention, treatment, and control are almost inseparable. It is useless to treat one member of a family at a time (D'Antoni and Sawitz, 1940). Treatment should cover not less than 10 days to reach all stages of development and preferably should be repeated after a week's rest. All members of the household should be treated at the same time and special precautions should be taken during this period with diapers, underclothing, night clothing and bed clothing to see that they are promptly washed. Extra precaution in the washing of hands, particularly those of children, should be stressed during this period. Piperazine citrate and piperazine adipate, which are also effective against ascariasis (Brown, 1954), are the drugs of choice.

The most common complaint resulting from pinworms is anal pruritis and this may be very troublesome. Fortunately, most individuals harbor the infection without any demonstrable sign (Weller and Sorenson, 1941). Perhaps the greatest significance of this infection is the evidence it affords of the extent to which feces reach the mouth under *good sanitary* conditions. This should be considered carefully before invoking the fly or the infected food handler as the source of any enteric infection, particularly the parasitic infections such as amebiasis.

## CONTAGIOUS DISEASES SPREAD BY GENITAL CONTACT

E. GURNEY CLARK, M.D., DR.P.H.

As a danger to the public health, as a peril to the family, as a menace to the vitality, health and physical progress of the race, the venereal diseases have been regarded as among the greatest of modern plagues and their control a most stressing problem of preventive medicine. Great strides have been made toward the solution of this problem but much remains to be done.

This group comprises five diseases—syphilis, gonorrhea, chancroid, lymphogranuloma venereum and granuloma inguinale—linked not because of similarity of causative agents, tissue reactions or symptoms produced but because the principal means of spread of each disease is by sexual intercourse, especially promiscuous sexual intercourse, as implied by their group name, “venereal.”

In spite of a comprehensive analysis of the importance of venereal diseases to the public health in 1876 by J. Marion Sims in his Presidential Address before the American Medical Association and his appeal for action on the part of boards of health, little was done until about 1912 (Parran, 1937). In this year the New York City Board of Health determined to treat the venereal diseases as any other highly communicable and infectious disease, dealing objectively with the hygienic factors of the problem from a public health standpoint. Similar action was taken by Montclair, New Jersey, in 1913. In the same year, the venereal diseases were made reportable by statute in Iowa, Kansas, Louisiana and Vermont. In 1914, Massachusetts began a control program based on early diagnosis and free treatment.

The advances made during World War I as a result of the Chamberlain-Kahn Act of July 9, 1918, establishing the Venereal Disease Division of the United States Public Health Service (Vonderlehr and Heller, 1946), were largely dissipated during the “back-to-normalcy” postwar period. Federal funds for venereal disease control dwindled from one million dollars per annum at the first year of the act to a mere one hundred thousand dollars in 1920. During the war and the 15 years following, a few states—notably Louisiana, Kansas, Montana, New Jersey, New York and Texas—established Divisions of Venereal Disease Control, and in some states these diseases were made mandatorially reportable by statute. Otherwise, venereal disease control remained quiescent until July, 1936, when Thomas Parran, then Surgeon General of the United States Public Health Service, blasted into the public’s consciousness again that the venereal diseases, especially syphilis and gonorrhea, were prevalent diseases which seriously menaced the public health. Modern venereal disease control began with his historic pronouncements.

Again the public was made aware that the venereal diseases are a constant menace to all classes of society unless everyone remains constantly alert. The history of preventive medicine can present no greater tragedy than the birth of a syphilitic child, nothing more pathetic than the newborn baby blinded by gonorrhea. Sadly enough, public health and medical measures alone do not suffice to allay such misadventures. The ultimate solutions to these problems transcend the use of medical and hygienic methods. The problems pervade law, education, social work, religion and economics. Ultimate control will depend upon the proper approaches undertaken and continued in each of these directions.

Measurable progress in venereal disease control has been made in the past 20 years, particularly in the field of education, case finding and treatment. However, we cannot avoid the conclusion that no matter how efficient diagnosis and treatment may be, the ultimate outcome to reduce these infections to an absolute minimum will depend upon the success in rendering cases noninfectious faster than the miscellaneous sexual relations spread them. More emphasis must be placed on coming spread of these diseases.

The venereal diseases are classified by state laws or regulations as syphilis, gonorrhea and chancroid. In addition, granuloma inguinale and lymphogranuloma venereum are reportable in some states. Syphilis and gonorrhea are of greatest importance because of their extensive prevalence and further because they are very serious infections with grave consequences. Gonorrhea has been characterized as the great preventer and syphilis as the great destroyer of life.

## SYPHILIS

Syphilis is a specific infection caused by the *Treponema pallidum*.<sup>\*</sup> It is acquired by intimate contact with infectious persons, with moist contaminated articles, and by congenital transmission. The initial lesion or chancre forms in the skin or mucous membrane at the site of entrance of the spirochetes. Syphilis runs a chronic course with lesions and symptoms of extraordinary diversity. It mimics many other diseases.

There are many striking things about syphilis, but nothing so striking as its persistence in spite of knowledge complete enough to almost stamp it out. Syphilis causes more mental and physical suffering than the other diseases of this category. It is preventable, even curable but these characteristics require that constant vigilance and control facilities be maintained.

Syphilis is a good illustration of the fact that it is much more difficult to control a disease transmitted directly from man to man than a disease transmitted by an intermediate host, or one in which infection comes directly from our environment. We have a certain amount of control over our surroundings and dominion over the lower animals, but the control of man requires the consent of the governed.

Civilization and syphilization have been close companions. Civilization must not be content until it has controlled syphilis as effectively as it has some other preventable infections. The effort must be persistent and in keeping with the need.

Economically, syphilis is not disabling in its primary and secondary stages. Persons in the early stages of the disease usually are not ill enough to cease work. But

<sup>\*</sup> First described by Schaudinn and Hoffmann in 1905 and called by them *Spirochaeta pallida*.

the infection is most communicable during this time. In the United States, 1 out of 10 cases are discovered during this stage. It is the late manifestations of acquired syphilis and all manifestations of congenital syphilis which endanger health and life. A considerable percentage of first admissions to the hospitals for the insane are due to syphilis. The estimated annual costs\* of uncontrolled syphilis are: 74,600 man years of disability (brain, heart, blindness); \$62,729,000 for maintenance (psychoses, blindness) and 115,830 man years loss of life expectancy.

The consequences of the disease are often more severe upon the offspring than upon the syphilitic parent. The infection is liable to be transmitted from parent to child and often with fatal results. If death does not ensue, the living consequences may be even more tragic.

The health officer should regard syphilis just as he does the other acute febrile exanthematous diseases. Because syphilis runs a slow and often chronic course, it is often placed in a class by itself. This is a mistake. Syphilis has its period of incubation, eruption and decline, just as measles and smallpox have.

**Historical Note.** There is an accurate historic record of the apparent spread of syphilis over the known world in a few years after 1495, and from that time it has everywhere become endemic. This is unique in epidemiology, for no similar record exists of the sudden establishment, if such it were, of a great disease among the larger part of the earth's inhabitants (Pusey, 1933; Hudson, 1946; Kemp, 1940).

Syphilis was not recognized as a clinical entity before the year 1493. It is said by some historians to have been brought by the crew of Columbus on his first voyage from Española, or Haiti. This is vigorously denied by others. The former insist that some of the returning crew accompanied Charles VIII of France in the autumn of 1494 with the army, 32,000 strong, which invaded Italy for the conquest of Naples. The "epidemic" began in Italy at this time and the disease spread quickly over Europe with the scattering of the troops. The French called it the Italian disease, and the Italians called it the French disease, or *morbus gallicus*. The present name of the disease was taken from a poem written by Fracastorius in 1530 entitled "Syphilis sive Morbus Gallicus," in which the symptoms are clearly described in the principal pastoral character, a swine-herd named Syphilus. The sexual nature of the infection was not recognized until some time after the "epidemic" outburst in 1494-1496. The history of the disease before this time is shrouded in difficulties and there is vigorous denial that syphilis was an American contribution to pathology.

\* V. D. Fact Sheet, December, 1954, Issue No. 11, U. S. Public Health Service.

† Sudhoff (Pusey, 1933) says that the story of the American origin of syphilis did not develop until almost a generation after the discovery of America and that it was first published in 1518 as an advertisement of the therapeutic value of guaiac introduced from San Domingo. He claims there was syphilis in Spain before Columbus' voyage and that it is quite possible some of the sailors had the disease. Moreover, he refutes the story of the terrible epidemic in the French army before Naples, and refers to the reports of Martino Sanuto, the Venetian Ambassador of Naples, which have been published in full. Virchow was unable to find lesions of syphilis in European and Oriental bones of the pre-Columbian age.

Bearing on the American origin of syphilis, according to Thom, bones from pre-Columbian graves offer evidence that syphilis existed among the aborigines before the Spaniards came to America. Williams considers that the evidence presented in a review of bones supposed to show syphilis, recovered during archeologic investigations, is sufficiently conclusive proof that syphilis originated in America. On the other hand, Hrdlicka found no authentic evidence of the disease in pre-Columbian skeletal material and concludes that the weight of evidence is against the American origin of syphilis. Nothing in either Indian tradition or Spanish writings

During the 200 years following this apparent outburst, much was learned about syphilis: signs and symptoms were recognized; its infectiousness proven; means of transmission were clarified; the duality of syphilis and gonorrhea were reaffirmed; lesions of congenital syphilis were described and treatment with mercury was widely used. In 1834, potassium iodide was introduced into the treatment of syphilis. Syphilis was differentiated from gonorrhea in 1852.

In 1903, Metchnikoff and Roux transmitted the disease to lower animals, demonstrated the prophylactic value of calomel injections, and also opened up a new field of animal experimentation. In 1905, Schaudinn discovered the *Treponema pallidum*, thus making diagnosis certain. In 1906, Wassermann, Neisser and Bruck introduced the Wassermann reaction. In 1909, Ehrlich, after many years of experiment, gave to the world salvarsan, a specific, synthetic spirocheticide, and opened the new science of chemotherapy. In 1911, Noguchi cultivated an organism resembling *Treponema pallidum*; and in 1913 demonstrated the spirochetes in the brain of a paralytic and in the cord of a tabetic.\* This unparalleled group of achievements, all the result of scientific work in laboratories, in 10 short years threw light on the cause, mode of transmission, pathology, treatment and prevention of the disease.

The history of chemotherapy for syphilis may be divided logically into three periods (Moore, 1945): (1) that of mercury, ending in 1909 with the discovery of 606 by Ehrlich; (2) that of arsphenamines, 1910 to 1943; and (3) that of the antibiotics beginning from the discovery of Mahoney and others (1943). Ehrlich's hope for a single curative dose of 606 was not realized partially because of serious toxicity of the drug. In 1917, Keidel and Moore in this country and Almquist in Scandinavia independently proposed a treatment plan embodying two new principles, the extension of treatment for longer than a year and the alternation of arsphenamine and a heavy metal (mercury at the beginning, in 1921 changed to bismuth). This has been the accepted method of treatment, both here and abroad, until recently. In 1933, a less toxic form of the arsenicals, arsenoxide, was reintroduced by Tatum and Cooper and in 1934 Chargin, Leifer and Hyman re-explored the effects of massive single dose arsenotherapy. The results were satisfactory but the increased risk to life was too great. As a result of these and other investigations, treatment schedules were developed based upon the researches of Eagle and Hogan whereby the complete therapeutic dose of mapharsen could be given in a period of 10 to 12 weeks with minimum toxic effects. The U. S. Army, using the information gained from these experiences, formulated a successful plan of complete therapy for early syphilis in a period of 26 weeks. These schedules were generally accepted in this country until the advent of penicillin in 1943. This is a new and powerful

at the time suggests the existence of the disease. Both Indians and Eskimos show a general lack of immunity when infected by Europeans.

Hudson (1946) presents further evidence against the theory of the Columbian origin. In view of the fact that pre-Columbian leprosy was considered highly contagious, was associated with sexual contact, had hereditary features and was said to be susceptible to mercury therapy, it is likely that the so-called leprosy of this period was actually syphilis since these are the characteristics of syphilis and not leprosy.

\* It is the general consensus among bacteriologists that successful cultivation of virulent *Treponema pallidum* has not been accomplished. Saprophytic spirochetes resembling it have been used in the picture.

addition to syphilotherapy. The evidence of 13 years of its use (1943 to 1956) is overwhelming as to its effectiveness, and as a weapon for public health control it is without parallel.

**Incidence, Prevalence and Trend.** The enormity of the syphilis problem has in recent years been brought forcibly to the attention of the medical profession and the general public. A most striking revelation of syphilis incidence for the country as a whole was brought to light by studies made by the United States Public Health Service and recorded by Vonderlehr and Usilton (1938). As a result of these studies, it was concluded that "syphilis strikes one in every ten adults." Although this statement is nondescriptive insofar as prevalence and the extent of the problem in limited areas are concerned, it emphasizes unquestionably that syphilis is a public health problem of major importance. This statement has been frequently misinterpreted to mean that 10 per cent of the population has syphilis. This is not the case. It means that if the syphilis attack rates for certain selected parts of the country were applied to the population of the country at large and these rates remained unchanged for a period of a lifetime, one out of every 10 persons might have been *expected to contract* syphilis before they reached the age of 50.

The actual *incidence* of syphilis, that is, the number of new cases occurring in a stated population during a specific time period, can only be roughly approximated. Such an approximation may be obtained in several ways: studies such as the one above (Vonderlehr and Usilton, 1938), "one-day surveys" (Parran and others, 1928), by notification of cases of early, i.e. primary and secondary, syphilis (U. S. Public Health Service, 1949), and by a calculation of discovery rates (Turner and others, 1943). The "one-day survey" seeks to provide information relating to prevalence as well as to incidence. In the chosen study area all treating agencies are asked to provide information concerning not only the number of persons under treatment and or observation on a given day (prevalence data) but also the number seeking diagnosis or treatment for the first time during a stated period of 30 days (incidence data). Such studies have not been carried out in recent years and as a result our present information on incidence and trend has been based almost entirely on the cases of primary and secondary syphilis reported to health agencies.

Such reported cases provide a measure of discovery, not of incidence. It is difficult to secure reliable information concerning the actual number of new infections which occur each year and equally as difficult to estimate the relationship of discovered to undiscovered cases. The occurrence of syphilis may remain constant or actually decrease in the face of an increasing rate based upon notification. The ratio of the discovered to the undiscovered depends upon the extent of venereal disease control practices, the degree of public enlightenment and interest, the availability of clinical facilities, the quality of syphilologic practice and perhaps many other factors. These vary from year to year and from locality to locality.

For the United States as a whole the rate of reported primary and secondary syphilis has varied from a high in 1947 of 75.6 to a low of 4.9 per 100,000 population (U. S. P. H. S., 1954). In every year during this period the number of early latent cases has exceeded that of primary and secondary cases. Therefore, we are compelled to assume that more than one-half of the cases of syphilis go into the latent stage undiscovered and unreported. The United States Public Health Service

imates that there occurred in the 48 states in 1954, 86,800 fresh syphilitic infections, 79,112 of which remain undiscovered.

**Prevalence.** The total number of cases of the disease existing in a specified area at any point of time, has been studied widely during the past few years. Such studies of prevalence have been based on serologic surveys of one or another kind upon "one-day surveys." Serologic surveys may be roughly classified into three groups: (a) those performed because of some medical abnormality (hospitals, clinics, doctors' offices); (b) those done on persons chosen on the basis of some social, economic or occupational grouping (food handlers, prisoners, blood donors, Selective Service registrants, college students); and (c) those performed on groups thought to be representative examples of specific communities. Studies of these three groups have shown prevalence rates to range from: group (a), 2.7 per cent among white females in a private practice in New York State to 49.4 per cent among Negro males in a private practice in Alabama; group (b), 0.2 per cent among white male students in college to 15 per cent among Negro applicants for marriage certificates in Virginia; group (c), 1.2 per cent among an unselected group of white males in Gibson County, Tennessee, to 23.6 per cent among Negroes in a serologic survey in Mississippi. One of the most significant presentations of prevalence in recent years has been the prevalence rates by color, age and residence per 1,000 subjects and volunteers examined in 1941. This is shown in Table 4-1 (U. S. Public Health Service, 1949).

Table 4-1. Syphilis detected in Selective Service examinations. Prevalence rate per 1,000 tested; age group 21-25

Age Group	White	Non-White	Total
21-25	10.1	191.2	30.1
26-30	20.9	293.7	54.4
31-35	37.7	357.2	85.2
ALL AGES	17.4	252.3	45.3

Prevalence and incidence studies throughout the country have, in general, shown that the rates among Negroes are higher than those among whites of comparable age, sex and economic groups. Among whites, the male rates are higher than those for females. Among Negroes, the total male rates equal those of females but there are some variations according to age. Females acquire their disease at an earlier age than males. Incidence is higher in the young, prevalence in the older, because of the effect of accumulation.

Measurement of the *trend* of syphilis, that is, the change in frequency from one time to another, involves all of the difficulties of measurement of incidence and prevalence and more, since changes in method of public health attack or actually in the definition of what constitutes a case of syphilis (presence or absence of positive tests, symptoms, lesions, etc.) may influence the calculated rate without reflecting actual change from time to time. It is generally agreed that the trend of syphilis is downward. There are those who believe that the newer treatment methods now in use are responsible for this and they foresee a continued and accelerated decline to the point where the disease will no longer be a problem. Others (Moore, 1951), although supporting the claims of decline, present evidence that this may be part

of a world-wide decline apparent since the middle of the nineteenth century, continuing since, and probably accelerated by modern control methods. There has been a tremendous decline in reported cases of primary and secondary, less marked in early latent and some in late, late latent and congenital syphilis since 1947 (see Table 4-2, page 284). Further evidence of decline is presented by Vonderlehr and Usilton (1943) after an analysis of data in a manner similar to their "one in ten study" of 1938. The chance of acquiring syphilis had dropped from 1 in 10 to 1 in 15. For analyses on a much smaller scale, Leiby and others (1947) suggest the use of prevalence rates among parturient women as an indication of trend. Turner and others (1943), searching for methods of measuring trend, found evidence that age-specific discovery rates among young adults (15-24) furnished a method which seemed promising.

**Mortality.** The actual syphilis death rate is unknown, not only because of the general disinclination of physicians to report syphilis as a cause of death, but also because the disease is so frequently masked in the general mortality statistics. If it be remembered that syphilis is the real cause of death in all cases of general paresis, locomotor ataxia, and aortic aneurysm, and in many cases of apoplexy, and is a contributory cause of death in a host of other conditions, including pulmonary tuberculosis, the real influence of syphilis on the general mortality rate may in some measure be appreciated. The extent of under-reporting deaths can be judged from a study by Nicoll and Bellows (1934). A confidential inquiry revealed that syphilis was stated on the original death certificate as a primary or contributory cause of death in approximately 49 per cent of cases in which it should have been so certified. The varying rates noted in the medical literature are essentially estimates modified by the personal bias and experience of individual observers.

"The sixth revision of the International Lists of Causes of Death," which became effective in 1949, reduced reported syphilis deaths by about 26 per cent. Rates adjusted according to the sixth revision show a decline from 11.1 per 100,000 in 1939 to 3.4 per 100,000 in 1953. These data give no indication of the differences that exist between the rates for the white and the non-white. These death rates fell steadily between 1939 and 1953: for whites, 7.7 to 2.5 and for non-white, 40.8 to 11.3 per 100,000 population. In 1945, 1 per cent of the total deaths from all causes were due to syphilis; of the white deaths, 0.72 per cent, of the non-white, 3.08 per cent (Kahn and Iskrant, 1948).

McCulloch (1930) in a review of 1,675 autopsies during the period 1909 to 1929, found that coronary sclerosis, angina pectoris, coronary thrombosis and myocardial infarction occur more often in the syphilitic than in the nonsyphilitic. In a series of 224 cases of chronic aortic disease reported by Cowan and Faulds (1929) syphilis was apparently the cause in approximately one third of the cases. In a series of 390 cases presenting macroscopic signs of cardiovascular disease, 60.3 per cent were syphilitic.

The well-studied autopsy material of the Yale University School of Medicine was reported by Rosahn and Black-Shaffer in a series of papers during the period 1943-1946 (Rosahn, 1947). The review of the world literature by these authors revealed that of 146,767 reported autopsies, 5.45 per cent were observed to be syphilitic at autopsy. The Yale material comprised 3,901 autopsies on persons over

years of age of which 390 or 9.7 per cent presented clinical, laboratory or autopsy evidence of syphilis infection. Of these, 390 individuals known to be syphilitic, treated and untreated, 23.7 per cent showed anatomic lesions of syphilis which were thought to have been the cause of death.

**Syphilis and Life Insurance.** Although the life insurance companies have taken an indefinite stand with respect to the insurability of syphilitics, the studies upon which this decision is based are inaccurate to an undeterminable extent. Schamberg (1945) reviews the literature on the prognosis of syphilis and concludes, "There is no evidence that syphilis adversely influences life expectancy except through the normal natural effect of its serious late manifestations, in particular those of the central nervous system and cardiovascular system." Heller and Bruyere (1946) conclude, after a study of a group of untreated syphilitic Negro males, that, "The life expectancy of a Negro man between the ages of 25 and 50 who is infected with syphilis and received no treatment for his infection is on the average *reduced* by about 20 per cent." Smith and Bruyere (1946), studying a group of treated syphilitics, conclude that, "The average life span of persons under routine therapy for syphilis is *shorter* than that of the uninfected person." Moore and Shamberg (1947) enumerate reasons why actuarial studies of the mortality of syphilis are incomplete, inaccurate and unsuitable for the determination of a policy in regard to the insurability of syphilitic persons, as follows: (a) known syphilitic populations are compared with supposedly nonsyphilitic populations, the latter of which contain an unknown proportion of syphilitics; (b) published mortality data do not take into consideration the prognosis of syphilis in the various stages, all types of syphilis infection being grouped together; (c) the exact mortality cannot be determined because of the inaccuracy of death certificates; (d) no consideration has been given to the fact that syphilis is primarily a disease of those in lower socio-economic groups which are subject to increased mortality risks from many other diseases; and (e) no consideration has been given to the adequacy of present-day treatment methods since the actuarial data that are available with respect to treatment relate to the preantibiotic era. This is a subject which requires much more careful study before a definitive answer can be given.

**Stages of the Disease.** Syphilis is divided into stages which are not well defined in time or sequence. The division is arbitrary, for there may be no sharp line of distinction and considerable overlapping is common. For example, while symptomatic neurosyphilis is usually one of the late manifestations it is occasionally observed early as acute syphilitic meningitis. In practice, the disease is classified as early syphilis and late syphilis.

*Early syphilis*, duration under four years, is subdivided into primary, secondary and early latent syphilis. *Late syphilis*, duration four years or more, is subdivided into latent syphilis, i.e., without clinical signs or laboratory manifestations except positive serologic test for syphilis, and late syphilis, including all the later manifestations of the disease, such as benign late (e.g., gumma of the skin and mucous membranes), visceral, cardiovascular, bone and joint syphilis, syphilis of the central nervous system (vascular, meningovascular, tabes dorsalis and general paralysis of the insane) and syphilis of the organs of special sense, particularly primary optic atrophy. Since invasion of the central nervous system usually takes place early in the course of the disease, asymptomatic neurosyphilis (positive cere-

prospinal fluid only) may be classified as early or late depending upon when the spinal fluid examination is performed. Congenital syphilis is similarly classified as early or late, the division being made at two years.

**THE CHANCRE.** The primary stage is the chancre, which appears within an average of about 21 days after exposure, forming at the site of entrance of the spirochete. The typical hunterian chancre \* is an indurated and indolent ulcer, usually single and painless. We now know, however, that it is frequently atypical and may be but a trifling lesion. In the absence of a careful inspection, the chancre may exist many days before it is detected, or even escape notice altogether. In the female the primary lesion is often located within the genital tract, is mistaken for an erosion and its true nature not recognized. Moreover, chancre on the external genitalia of the female is frequently inconspicuous and indurated but slightly if at all.

*Extragenital infection* is by no means rare. Unusual location of the chancre diverts suspicion which would be aroused by a sore on the genitals.

*Generalized infection becomes fully established even before the appearance of the chancre.* It has been proved by animal experimentation that the spirochete can penetrate the unbroken mucous membrane of the rabbit and be found within the adjacent lymph glands within 24 hours after inoculation: this in marked contrast to the slowness of the appearance of the chancre.

The chancre teems with *T. pallida* which may readily be seen with the darkfield illumination. This is the method of earliest diagnosis. The serologic reaction usually does not become positive until from several days to several weeks after the appearance of the chancre. It is important, therefore, to examine every genital sore by darkfield. The initial lesion of syphilis often resembles a chancroid, and sometimes may seem to be only a simple abrasion. Mixed infections frequently occur. The primary lesion of syphilis usually disappears spontaneously without treatment before the disappearance of the secondary lesion, or may persist throughout the secondary phase.

*Secondary Stage.* The secondary manifestations usually begin from four to six weeks after the appearance of the chancre but may be delayed for a year or more. The symptoms are generalized or localized eruptions on the skin and mucous membranes, enlargement of the lymph nodes, and alopecia; slight fever, headache, vague pains in the bones and joints and sore throat are also common constitutional symptoms. In a large number of cases these manifestations are so mild they escape notice altogether, or may never occur at all. When they do occur, they persist for a variable period of time (from a few days to several months) and, in turn, disappear spontaneously without treatment.

These early lesions of primary and secondary syphilis are characterized by relatively mild tissue reactions and by the presence of numerous *T. pallida*. The lesions are superficial, tissue is not destroyed, and healing occurs usually without scarring. With healing, the organisms disappear from the skin and mucous surfaces.

\* John Hunter accidentally inoculated himself and purposely delayed treatment in order to study the disease in his own person. He accurately described the initial sore which has since been called the hunterian chancre. He differentiated syphilis from chancroid, but confused it with gonorrhea in 1786. Ricord in 1838 wrote a memorable treatise overthrowing Hunter's mistaken ideas and established gonorrhea and syphilis as separate diseases.

**LATENCY.** Upon the spontaneous healing of the early manifestations, there ensues a period of unpredictable length during which there are no outward signs of syphilis and during which the infected individual is recognized as syphilitic only by means of positive blood serologic tests. This period of latency may persist for a few months or it may be prolonged throughout life. The apparent symbiotic relationship between the invading organism on the one hand and the infected host on the other may be interrupted during the first few years of infection by one or more periods of spirochetal aggressiveness resulting in infectious relapsing lesions of the skin or mucous membranes. These relapsing lesions are characterized by their clinical similarity to those of secondary syphilis and are highly infectious. After the first few years this clinically latent relationship between organism and host may be interrupted by progression of the disease in the skin, cardiovascular system, bone, joints, viscera and central nervous system resulting in the well known manifestations of this disease.

**LATE SYPHILIS.** This stage or period is subject to all manner of variations, from clinical latency to symptomatic late syphilis, a fact that causes this disease to be called "the great imitator." The term latency refers to clinical latency, that is, the absence of outward manifestations of the disease. During this variable period, one of three immediately undetectable phenomena may be taking place beneath the surface. One is a complete triumph for the human host—the disappearance of all anatomic and bacteriologic evidence of infection—so that at autopsy, when the patient finally dies from some other cause, all evidence of syphilis is absent. In another, the reaction of the host to the organism may be considerably altered, the tissues developing the capacity to react in a manner totally different from that of the first few years. Instead of superficial, insignificant lesions rich in treponemes he may develop large, obdurate, destructive lesions which contain relatively few organisms, the gumma. Third, there may be a slowly progressive chronic inflammation in various tissues, particularly the cardiovascular and nervous systems, with subsequent fibrosis and ultimate impairment of physiologic function in these organs.

The gummas occur at varying time intervals following infection but are usually the first of the late manifestations to appear. The incubation period of symptomatic late syphilis varies with the type but, in general, clinical evidence of such involvement is more prominent in the second and third decades of the disease. Cardiovascular lesions become manifest even more slowly, their incidence reaching a peak usually in the third decade following infection. Any or all of these manifestations may be present in a single individual.

**Diagnosis.** *Early diagnosis followed by prompt and adequate treatment are the most practical and promising measures for the control of syphilis.* The clinical symptoms are often atypical and elusive, yet careful clinical examination combined with judicious use and interpretation of laboratory tests, will result in early diagnosis in the majority of instances.

**BY DARKFIELD EXAMINATION.** The lesions of early syphilis, rich in *Treponema pallidum*, provide the only means of *conclusive* diagnosis. Spirochetes in serum from the chancre, from the scarified skin lesions, from the mucous patches and condyloids of secondary syphilis, and in tissue juices aspirated from the satellite buboes of primary and secondary syphilis, can readily be seen under darkfield illumination. Because of the similarity of spirochetes normally found about the genitalia and in

the mouth, the identification of the true *T. pallida* should not be in the hands of the tyro. Many clinicians will not rely upon darkfield examination from mouth lesions done by the expert himself. Darkfield examination should be applied as a routine to every genital sore. A single negative finding is not conclusive and the examination should be repeated daily for several days. Local antiseptics should not be applied until the diagnosis is established for they may destroy the surface spirochetes. Bathing the lesion in simple salt solution enhances the probability of finding the organisms. The younger the lesion, the more readily are the spirochetes demonstrated. Puncture of the satellite bubo affords a simple means of early diagnosis when the examinations of chancre serum prove negative. The richest sources of *T. pallida* are the condylomata of secondary syphilis.

**BY EXAMINATION OF BLOOD SERUM.** The blood serologic tests become positive only after general invasion by the spirochetes has taken place. At the time of the first appearance of the chancre these tests are practically always negative. In the great majority of instances, the test will become positive within the first 3 to 14 days following the appearance of the primary lesion, this time interval depending upon: (a) the appearance in the blood of "reagin" in sufficient amounts to be detected, and (b) the sensitivity of the serologic test being used. A single unsupported negative test is not sufficient to rule out syphilis, nor is a single unsupported positive test sufficient to make the diagnosis of the disease.

In spite of the fact that numerous serologists have given their names to the serodiagnostic tests for syphilis (Eagle, Kline, Kahn, Hinton, Mueller, Meineke, Laughlin, Ide, Mezzini, Chediak, Wassermann, Kolmer, Wadsworth and others) these tests are based upon a *single principle* and upon only *two basic procedures*. The numerous names represent modifications of these basic procedures. The underlying principle is related to the fact that there appears in the blood following syphilis infection (and following other infection, for that matter) an antibody-like substance called "reagin." This "reagin" has the property of combining with fine divided particles of mammalian tissue, particularly beef heart (the antigen). The two basic procedures are devised to determine whether or not such a combination has taken place and are known as *complement fixation* and *flocculation or precipitation*. All of the serologic tests for syphilis are modifications of one or the other of these detecting procedures. Not only do these tests vary tremendously in sensitivity and specificity but also the individual tests may vary in performance from day to day.

In view of the nonspecificity of the antigen used in the performance of the tests, it is not at all surprising that false-positive reactions are frequently encountered. Among the diseases and conditions that have been shown to produce false-positive reactions with these tests are the following: infectious mononucleosis, malaria, leprosy, vaccinia, upper respiratory infection, chancroid, lymphogranuloma venereum and others. False-positives may also be technical ones or may result from the fact that a certain number of normal individuals have this antibody-like substance circulating in their blood.

After the widespread use of quantitation (titration) of reagin, which was an essential adjunct to control and to the evaluation of treatment, the most significant advance in diagnosis has been the development of the treponemal immobilization test (TPI). The specificity of this test makes it useful in distinguishing biologic false reactors.

**BY EXAMINATION OF THE CEREBROSPINAL FLUID.** Invasion of the central nervous system takes place early in the course of the disease and can be detected by examination of the cerebrospinal fluid many years before involvement occurs. The examination should be performed for every patient infected with the disease and could consist of a cell count, a determination of total protein, performance of the colloidal gold test, and a quantitative complement-fixation test.

**Methods of Transmission.** Transmission of syphilis depends: (a) upon satisfying the biologic requirements of the organism; (b) upon certain conditions of the host-parasite relationship; and (c) certain habits and customs of people.

The biologic requirements of the *T. pallidum* explain why syphilis is a disease of intimate contact (Clark, 1948). This organism is a very fragile one, unable to resist drying, unfavorably affected by many common agents, and is said to be killed by the weakest antiseptics and to be killed more quickly by soap solution than by many strong disinfectants. It dies under blood bank conditions in 72 hours but will survive rapid freezing to  $-76^{\circ}\text{C}$  for a year. It has been found inactive for 26 hours in syphilitic autopsy material. It is immobilized at  $41^{\circ}\text{C}$  ( $105.6^{\circ}\text{F}$ ) in two hours. These facts have a direct bearing upon the behavior of the organism in nature. Only on the mucous membranes about the genitalia and the mouth are conditions consistently found in man which permit its survival for periods long enough for invasion.

As stated by Stokes and others (1944), "It is not a divine moral purpose, or a satanic punitive ingenuity that connects syphilis with genital activities, but a mere biological accident no more significant in the last analysis than the fact that potatoes grow in sandy loam."

The host-parasite relationship (Clark, 1948) must be such that: (1) it is possible for the organism to *escape* from the infected host in sufficient numbers; (2) the organism must be appropriately *transmitted* under conditions which satisfy its biologic requirements; and (3) it must gain *access* by finding appropriate portals of entry in the new host. Moist surfaces provide the avenues by which the organisms escape from their reservoir, and intimate contact by sexual intercourse or kissing furnishes the conditions necessary for conveyance to a corresponding portal of entry in a new host. The newly implanted micro-organism becomes established under conditions of moisture, warmth and low oxygen tension and may penetrate intact mucous membrane.

Moist infectious lesions are present only during primary, secondary and recurrent secondary syphilis. Body fluids and secretions (saliva, semen, usual common vaginal discharges) from syphilitics in various stages of the disease have been studied experimentally and frequently have been shown to contain the organisms during the early stages of syphilis when lesions are present, but only rarely during the later stages when there are no obvious lesions. Blood has been shown to be infective chiefly during the incubation period and while primary and secondary lesions are present. Transfusion syphilis has resulted from the use of donors with early lesions or in the period before their occurrence or immediately after their disappearance. The usual explanation of *in utero* infection at the present time is that occasional spirochetemia occurs and results in the placental transfer of organisms to the fetus. This has not been proven experimentally.

Intimate contact with primary and secondary lesions provides the most favor-

able conditions necessary for transmission. However, despite the presence of infectious lesions, transmission following unprotected sexual exposure does not invariably take place.

Klingbeil and Clark (Clark, 1948) found that 18 of 97 marital partners (18 per cent) escaped infection although they were exposed sexually to early infectious lesions. Other studies of conjugal syphilis have contributed to the knowledge of transmissibility. O'Leary and Williams found no instance of conjugal infection among spouses of 25 patients (13 untreated) who had acquired syphilis four or more years before marriage.

Paternal transmission of syphilis direct to a fetus does not occur. Congenital syphilis is a result of maternal infection. Thus Colles' Law, concerning nonsyphilitic women and their syphilitic offspring, and Profeta's Law, concerning syphilitic women and their nonsyphilitic offspring, have no place in modern syphilology.

Under certain conditions the syphilitic pregnant woman can transmit syphilis to the fetus in utero after, but not before, the fourth month of pregnancy. Cellular as well as humoral factors within the host are thought to be responsible for this. Transmission to the fetus depends upon the duration of infection in the mother, the number of previous pregnancies and the amount and type of treatment received. A child of a treated or untreated syphilitic mother may be born: (1) *nonsyphilitic* with a negative serologic test or a positive test which becomes negative in a short time; (2) *syphilitic* with a negative or positive serologic test and no signs of the disease until several weeks after birth; (3) *syphilitic* with a positive test and with signs of the disease at the time of delivery; or (4) *dead* as a result of syphilitic infection.

Transmissibility, therefore, depends upon: (1) the duration of infection; (2) the presence of moist lesions; (3) the infectiousness of secretions; (4) tissue reservoirs of organisms; (5) intimate contact with the organism in sufficient number; and (6) accessible portals of entry in the susceptible individual which satisfy the biologic requirements of the organism.

The chance of exposure to any micro-organism is dependent upon habits and customs of the people in relation to that specific organism. This relationship in syphilis is such that sexual behavior and promiscuity of the population determine the transmission of the disease. High prevalence and high incidence rates usually are a reflection of high promiscuity rates since the frequency of infection varies directly with the frequency of exposure to the *T. pallidum*.

**Immunity.** There is no known natural immunity to syphilis in man. It is convenient to divide considerations of acquired immunity into two parts: (1) resistance or immunity of the infected individual to new organisms introduced from without, i.e., reinfection or superinfection; (2) resistance to the organisms already present in the tissues.

1. **RESISTANCE TO ORGANISMS FROM WITHOUT.** Experimental reinoculation of an already infected but untreated man or animal results usually in a lesion which takes the appearance of those present at the time of the reinoculation. If lesions have disappeared, no lesion at all ordinarily follows reinoculation. Immunity has been established.

When infected animals or human beings are treated, resistance to reinoculation is related to the time at which treatment is started. For example, reinoculation

bits treated before the forty-fifth day of their disease usually results in the development of a second chancre and if treatment is given between the forty-fifth and fiftieth day, a second chancre not infrequently results from reinoculation. If, however, treatment is deferred until after the ninetieth day (during the stage of latency) reinoculation does not usually result in a new infection. The immunity that has developed can be overcome by greatly increasing the size of the inoculum of a homologous strain or by using a heterologous strain.

2. RESISTANCE TO ORGANISMS WITHIN. There is no question that resistance to syphilitic infection actually does develop. This is demonstrated by the evolution of untreated disease when early lesions of primary and secondary syphilis heal spontaneously. In a short period of time, lesions which literally swarm with organisms have disappeared and the organisms remain in relatively small numbers in all organs. Thus, there is established an equilibrium between the organism and the defense mechanism of the host. This equilibrium may be turned in favor of either the host (spontaneous cure) or the parasite (infectious relapse in early syphilis or progression into late syphilis).

There is at this time no unanimity of opinion among syphilologists regarding the criteria for differentiation between syphilitic relapse and reinfection. However, the previously held rigid standards for diagnosis of reinfection have been questioned in recent years as a result of observations on patients treated intensively. It is the consensus that reinfection occurs much more frequently than was thought to be the case 20 years ago.

Marriage and Syphilis. The state of Louisiana in 1954 became the forty-second state or territory to provide for the *premarital examination* for both bride and groom. Thus, most of the states and territories have case-finding and protective laws, leaving only eight states plus the District of Columbia, Puerto Rico and the Virgin Islands without protection. Forty-two states, Alaska, Hawaii and the Virgin Islands also protect babies from syphilis by laws providing for *prenatal blood tests*, the District of Columbia, Puerto Rico and six continental states still being without legislation (Public Health Service Publications Nos. 383 and 365).

Whether one supports this type of legislation or not, it cannot be denied that 500,000 tests—estimated by the Public Health Service to have been performed annually under these laws—serve in some measure to find cases, save lives and prevent disaster.

In general, these laws are devised to discover applicants for marriage who may have infectious or potentially infectious syphilis. In only one state (Missouri) is a laboratory report and an affidavit on the part of the applicant sufficient for the issuance of a license; some states permit marriage irrespective of the results of the laboratory test if the woman is pregnant (e.g., South Dakota); one state (Kansas) bars marriage (subject to appeal) of syphilitics; and in several states evidence of a negative test and examinations are required of each applicant. Four states require the State Health Department to grant permission for issuance in cases of applicants with positive serologic tests; three states (Virginia, Massachusetts and Montana) require only that the applicants be told by the physician that syphilis is present in one or more of the applicants and that the possible consequences of the disease be explained. In the remainder of the states having such laws, a license is

granted following a serologic test and a statement by the physician that the disease is not communicable or in a stage which might become communicable.

Because of the vagaries of this disease and the differences of opinion which exist in respect to the duration of its infectiousness, the premarital examination laws have been misinterpreted by physicians and applicants alike. In some instances certification has been refused on the basis of a positive blood reaction alone. It should be stated that the intent of these laws is not to prevent permanently the marriage of persons with syphilis but only to delay the marriage of those with communicable or potentially communicable syphilis until the disease has been rendered permanently noninfectious. Two objections are obvious: (a) that a bar to marriage is not a bar to sexual relationships, and (b) that it is difficult or impossible scientifically to state just when syphilis becomes noninfectious.

Under these laws, the physicians are required to answer two questions: (1) Does the candidate have syphilis? (2) If the candidate does have syphilis, is it infectious or potentially so? The answer to the first question lies in the judicial interpretation of standard diagnostic procedures: a full history, a careful clinical examination, darkfield examination, and confirmed or repeated serologic tests for syphilis. If all these procedures are carefully done and are found to be negative, it is safe to assume that the candidate does not have syphilis. It cannot be emphasized too frequently, however, that a negative blood reaction does not by itself rule out syphilis. As a matter of fact, the blood reaction may be negative in the presence of highly infectious syphilis (seronegative primary syphilis). Furthermore, there are many conditions other than syphilis which can occasionally give rise to positive blood tests. A single positive serologic reaction, unsupported by clinical evidence or history of syphilis, should not be interpreted as diagnostic of the disease but only as indication for more careful investigation.

After a diagnosis has been established, the laws of most of the states and, of course, good medical practice obligate the physicians to form an opinion as to whether or not the disease is communicable or potentially so. This judgment depends upon an understanding of the biologic course of the disease and the vehicles and conditions of its transmission (see above). In general, it can be said: (a) that the early lesions of syphilis are highly infectious; (b) early latent syphilis is potentially infectious; (c) syphilis of five or more years duration is probably not potentially infectious (except in utero); and (d) late syphilis is not infectious. Applicants with congenital syphilis may be certified provided it can be established that a reinfection has not taken place.

If the diagnosis of syphilis is established and if the applicant is considered to be in an infectious or potentially infectious stage, treatment should be instituted in the amount and type considered adequate for the particular treatment method utilized, before the physician can legally certify noncommunicability. The majority of the laws of this kind do not provide recommendations for the situation in which one applicant is found to have syphilis in a noncommunicable state or for the instance where both applicants are found to have the disease. In the first instance, although there may be no danger of transmission to the marital partner, there is the ultimate possible danger of progression of the disease, in the absence of adequate treatment. Central nervous system or cardiovascular system syphilis can bring serious

financial disaster to the family. In the second instance, it is not possible for the disease to be transmitted to the marital partner already infected, but there may be risk in such instances to the offspring of such a union.

**The Curability of Syphilis.** Cure in syphilis means: (1) that the patient becomes and remains symptomatically well; (2) that he is incapable of transmitting infection to others; and (3) that in addition he becomes and remains serologically negative as to blood and spinal fluid (Moore, 1943). Syphilis is a curable disease both therapeutically and spontaneously. The extent of spontaneous cure is a matter of conjecture, estimates varying between 10 and 30 per cent of those detected and untreated. Cure as a result of specific treatment depends upon the time of institution of treatment, and on the amount and type of the specific therapeutic agent. Cure may be interpreted as biologic, serologic or symptomatic. To the physician and the biologist, cure is interpreted in its biologic and serologic sense, that is, biologically the eradication of the last remaining spirochete, so that the patient, insofar as his syphilitic infection is concerned, is in the same state as before he acquired the disease. Serologic cure means the laboratory tests of the blood and spinal fluid become and remain negative. On the other hand, it is symptomatic cure which is of interest to the patient. This means that the patient becomes and remains well, so far as his syphilis is concerned, for the remainder of his lifetime. The patient wants the answer to the question, "What are my chances of becoming and remaining well with no further trouble from this disease?" This depends upon the adequacy of treatment and the patient's willingness to follow obediently the instructions of his physician. Under these circumstances at the present time the probability of cure approaches 100 per cent.

**Prevention.** Early diagnosis and prompt treatment are the most promising and practical measures to control syphilis. To accomplish this, education is fundamental. After reporting and the epidemiologic study of every case of early syphilis in order to find possible foci of infection and spread are feasible and have been shown in practice to control the spread of the infection and to disclose early cases which otherwise would be missed. Early diagnosis and prompt treatment are methods of preventing the spread of syphilis, but our duty in preventive medicine is to make every effort to prevent infection in the first place.

**Summary.** Despite great progress in control, syphilis today (1955) is an important health problem because so many cases are undetected during the early stages. It is primarily a disease of youth, but its effects are manifest in later life. Estimated annual costs of uncontrolled syphilis are: 74,600 man years of disability; 2,729,000 for maintenance of the syphilitic blind and mentally ill; \$108,558,000 loss of income and of state and federal income tax from patients with syphilitic diseases; and 115,830 man years loss of life expectancy. It lowers the standard of health and contributes enormously to lowered individual economic efficiency. It causes a large proportion of the abortions and miscarriages. It is a frequent cause of the disintegration of home ties and is a destroyer of happiness and the source of untold suffering. Nevertheless, it is largely a preventable and curable disease. It is one of the few diseases for which there is a specific remedy. It is preventable yet it continues to spread, due largely to the fact that it is acquired chiefly through sexual contact and, therefore, becomes a hidden disease. The control of syphilis is centered about early diagnosis, prompt treatment and the provision of adequate

diagnostic and treatment facilities; upon finding and treating foci of infection. The success of these measures depends upon education of the medical profession and the public.

### GONORRHEA

Next to measles, whooping cough, chickenpox and the common cold, it has been estimated that gonorrhea is the most prevalent of the acute infectious diseases (Top, 1947). Among the venereal diseases it is by far the most prevalent, occurring approximately six or seven times more frequently than syphilis. In fiscal 1954 there were reported to the United States Public Health Service 239,661 cases of gonorrhea as opposed to 7,688 cases of primary and secondary syphilis (U. S. Public Health Service, 1954).

Recent developments in the therapy of gonorrhea have created such conflicts of opinion among physicians and health officers as to pose questions such as, "Is gonorrhea control a public health function?" (Kiesselbach, 1949). This, in spite of its great incidence and in view of the fact that the complications of the disease *per se* have not changed.

Gonorrhea involves not only the infected person, but often the innocent also in tragic consequence. Married consorts infect each other, often resulting in disruption of the home and in the social calamities which follow; and in wage earners it causes loss of health and lowered efficiency. A high percentage of the cases of sterility in women is due to gonorrhea and much of the pathology coming to the attention of gynecologists is a consequence of this infection. One of the most calamitous sequelae to gonorrhea in the pregnant woman is the infection of the eyes of the baby at the time of birth. Ophthalmia neonatorum in the majority of instances is due to the gonococcus.

In any consideration of gonorrhea from the medical or the public health standpoint, the facts logically arrange themselves into four distinct categories: (a) gonorrhea in the male; (b) gonorrhea in the adult female; (c) gonorrheal vulvovaginitis in children; and (d) gonorrheal ophthalmia neonatorum (Nelson and Crain, 1938).

**Historical Note.** The story of the exact origin of the disease is unknown, but what appears to be gonorrhea is mentioned in the fifteenth chapter of the Book of Leviticus in terms of "a running issue out of his flesh." Hippocrates in 460 B.C. knew of the disease and Galen, a Greek physician, in 200 A.D. applied the name to the disease by which it has been known since. His belief was that the discharge was an involuntary flow of semen; hence the name (gonos, seed; rhoia, flow). Its relationship to sexual intercourse was not realized for many years, and it was the latter part of the nineteenth century when it became known and accepted as a communicable disease (Nelson and Crain, 1938). Although Hill distinguished syphilis from gonorrhea in 1790, the two diseases were immediately confused by the classic experiments of John Hunter. He "proved" that they were variations of the same disease by the demonstration of the development of syphilis following the inoculating of his skin with urethral discharge from a patient with gonorrhea. In view of our present knowledge, it is clear that the patient had either both gonorrhea and syphilis or that the urethral discharge was caused by a hidden urethral chancre and not by the *gonococcus*. It was not until 1831 that Ricord

nitely separated syphilis from gonorrhea and it was years later, in 1879, when Loeffler isolated the *gonococcus* and proved that it was the etiologic agent.

**Incidence, Prevalence and Trend.** The actual prevalence of gonorrhea in the general population of the United States is unknown and even approximations are difficult because of the amazingly indifferent attitude toward this disease in the general belief that it is seldom, if ever, attended by serious consequences. Many people consider that it is "no worse than an ordinary cold." The perfection of modern treatment has added to this misconception.

Notifications to state boards of health are indeterminate. There is great laxity in this respect due to the reluctance of physicians to report cases even though notification is required by law. During the five-year period 1950 to 1954, 1,303,602 cases of gonorrhea were reported to the United States Public Health Service in 48 states, comprising an annual average of 260,720 cases (United States Public Health Service, 1954). The most disturbing aspect of gonorrhea incidence is the high proportion of young people who acquire the disease. The highest rates are seen among the 20-24 age group (almost 1 per cent in 1953). Even more startling is the rate among teen agers. In 1953 this rate was 480 per 100,000 aged 15-19, or among every 200 teen agers in the United States.

**Diagnosis.** The diagnosis of gonorrhea is not easy. Microscopic examinations of urethral, vaginal or intracervical smears, showing Gram-negative diplococci, pairs and shaped like coffee beans, within the polymorphonuclear cells, even in the acute cases may not be gonococci. Unquestionable diagnosis can be made only by culture and the utilization of sugar reduction tests. The *gonococcus* alone ferments glucose, not maltose. The *gonococcus* belongs to the Neisserian group of organisms including the *N. meningococcus*, *N. catarrhalis*, *N. flava*, *N. sicca*, and *N. gonorrhoeae*. The individual species are usually differentiated by their respective abilities to ferment different sugars with the formation of acid, colony forms, growth requirements, and serologic reactions.

In acute urethritis of the adult male, accurate diagnosis is no longer a simple matter because other organisms are known to produce nongonorrheal urethritis. In the female, however, a great amount of patience must be expended sometimes before satisfactory bacteriologic proof is obtained. It is in these cases where the culture method has proved so valuable. The culture method found so practical is that described by Carpenter (1936).

The difficulties inherent in diagnosis of gonorrhea are demonstrated in a review by Kiesselbach (1949). Of 400 patients referred to a Rapid Treatment Center with a diagnosis of "gonorrhea," only 39.4 per cent were found to have gonorrhea when subjected to confirmation by culture and fermentation tests. Of 213 cases already diagnosed as gonorrhea on clinical and slide evidence by local health departments, only 46 per cent could be confirmed as actually having gonorrhea. Of a large number of girls between the ages of 11 and 18 admitted to a state reformatory, 80 per cent were found to have positive clinical and slide tests for "gonorrhea." A test of these individuals using the carbohydrate fermentation tests revealed none of them to be infected with this disease. A large general hospital in the South found, on routine vaginal examination of all infant females, that the great majority had clinical signs, and slide tests were positive for "gonorrhea." When carbohydrate fermentation tests were done, not one was found to be infected with this disease.

A venereal disease control officer of a New England state reported that between January and April of 1948, 50 per cent of the male patients coming to his central clinic with a urethral discharge were found by the laboratory to be nongonorrheal.

As long as such difficulties in diagnosis continue and as long as two thirds of those estimated to be infected each year do not come to medical attention, gonorrhea will continue to remain a public health problem.

**Transmission.** As in syphilis, transmission of gonorrhea depends upon: (a) satisfying the biologic requirements of the organism; (b) certain anatomical characteristics of the human host; and (c) the habits and customs of people. This is another micro-organism that requires moisture to live and thus has little vitality outside of the human host. And its transmission depends upon the interchange of moisture, directly or indirectly, from the infected to the uninfected host. Whether or not the micro-organism invades the new host depends upon the type of tissue upon which it is deposited. It does not penetrate the skin. Of the three types of epithelium found in the genital tract—stratified squamous, columnar and transitional—only the columnar and to some extent the transitional are susceptible to invasion by gonococci. Thus, invasion by the *gonococcus* takes place only in those tissues composed of columnar epithelium or of the transitional type. This limits the manifestations of gonorrhea to only a few places of the human body.

**Gonorrhea in the Male.** After an incubation period of three to nine days, a thick, yellow purulent discharge from the anterior urethra makes its appearance. Spread to the posterior urethra, the prostate and other parts of the body takes place after varying lengths of time. Although the disease is a self-limited one, complications occur, such as epididymitis, arthritis and prostatitis.

**Gonorrhea in the Adult Female.** The disease in the female is described as having three stages: the stage of initial infection, that of pelvic invasion, and the stage of pelvic degenerative changes.

The first stage begins a few days after exposure, usually less than a week, and is manifest in most cases by mild burning or smarting. Examination may reveal mild changes. In only occasional instances are these early signs and symptoms severe. The next stage, that of pelvic invasion, may be delayed until after the first or second menstrual period following infection. The first, and sometimes the only, signs that the disease has passed upward beyond the cervix is a menstrual period which begins too soon or lasts too long or the flow is unusually heavy. There are wide variations in these manifestations. There may be no evidence of extension. As the infection extends into the Fallopian tubes it causes salpingitis and frequently the pus produced in the tube spills into the pelvic cavity and acute pelvic peritonitis results. Symptoms may be mild or severe. This acute infection of the pelvic contents subsides after a short period but usually a chronic low-grade infection may persist for many years. The third stage is actually the aftermath of infection. It damages organs of reproduction and accounts for much "female trouble." It causes abdominal operations and is a cause of sterility. The mild early symptoms and the difficulties of diagnosis in females make gonorrhea in the female still a considerable health problem despite advances in treatment.

**Vulvovaginitis in Children.** This is an inflammatory process involving the urogenital tract in females, chiefly the vulva and vagina, characterized by swelling and redness of the mucous membranes and by purulent discharges of varying

ee. It may be caused by a variety of organisms, including the *gonococcus*. It is not strictly a venereal disease but its history was inseparably linked with gonorrhea until a few years ago. Among other contributions, that of the New York City Department of Health reported by Cohn (1942) showed that only a relatively small proportion of so-called "gonococcal" vaginitis (22.2 per cent of the latter cases) was due to infection with the *gonococcus*. It was found that smears were generally not reliable and that only cultures allowed a direct diagnosis. Of considerable interest was the fact that of the untreated group, 87 per cent became cured spontaneously by the twenty-eighth week after the beginning of observation. This tendency to spontaneous cure indicated that the infected tissue had the natural tendency to heal. Healing was not hastened by estrogenic therapy.

Discharges from infected persons provide the avenues of infection and the mode of communicability is determined by the presence of the causative agent in the discharges. Prevention depends basically on the control of gonorrhea in the population and specifically on proper supervision of institutions for children with and enforcement of hygienic principles. Isolation is recommended for the first 24 hours after the administration of antibiotics (American Public Health Association, 1955).

**Ophthalmia Neonatorum.** Ophthalmia neonatorum includes every type of purulent inflammation of the conjunctiva which occurs during the first three weeks of a baby's life. This is an acute infection caused by a variety of infectious agents. In the past a great majority of these infections was due to the *gonococcus*. At the present time the most frequent type of infection is inclusion blenorrhea, caused by virus. The offending organism usually gains access to the conjunctiva during birth as the baby's head descends through the infected birth canal of its mother. The incidence of gonorrheal ophthalmia neonatorum is difficult to determine at the present time, yet there is no doubt that there has been a remarkable reduction in the occurrence of this condition and its complication (especially ulceration of the cornea and blindness) since the introduction of the Crede silver nitrate method of prophylaxis (Top, 1947). This procedure, required by law in 44 states, is carried out as follows: clean eyes with cotton and boric acid solution, separate the lids and instill one to two drops of 1.0 per cent silver nitrate solution, taking care that the solution does not fall on eyelid or cheek. The solution is then washed out with saline after two minutes.

In spite of the success of this procedure in preventing blindness, there has been persistent criticism of the use of a strong corrosive in the eyes of the newborn. Aside from the irritation as a result of silver nitrate, failures in protection have often been reported. Numerous substitutes have been proposed but none has seemed to offer the same advantages as silver nitrate until the introduction of the antibiotics. These substances are now being given careful trial in an attempt to find a safe and reliable prophylaxis for this disease (Allen and Barrere, 1949).

## CHANCROID

Chancroid, or soft chancre, is an acute specific, local, autoinoculable and contagious venereal disease, caused by the streptobacillus of Ducrey. The ulcers are often multiple and confer no immunity. Chancroids are peculiarly liable to mixed

infections and are apt to become phagedenic. Infection is usually acquired by sexual contact, but accidental nonvenereal inoculation does occur.

The infection develops as a small erythematous lesion within three to five days after exposure, at times later, which shortly develops into a papule. This soon breaks down, forming an ulcer with ragged undermined edges, accompanied by an abundant, purulent secretion. The ulcers are painful and bleed easily. There is usually no systemic reaction and uncomplicated cases manifest a tendency to spontaneous healing by cicatrization extending from the edges toward the center. In about 50 per cent of cases there develops adenitis of the inguinal lymph glands and buboes, which are painful and often suppurate. The inflammation and ulceration on the penis may lead to phimosis, destruction of the frenum, gangrene and phagedena.

**Diagnosis.** From the public health standpoint the differentiation between chancroid and syphilis is paramount. This may be accomplished by darkfield examinations of serum obtained from the base of the ulcer, repeated as frequently as may be necessary. Negative darkfield tests should be followed by repeated blood serum tests.

The diagnosis of chancroidal infection may be accomplished by one or more of the following methods (Greenblatt 1943): (1) recovery of the *Hemophilus ducrei* from the lesion by spread or culture; (2) intradermal reaction utilizing an antigen made from bubo pus or the cultured organism; (3) biopsy; and, finally, (4) by exclusion, after utilizing clinical and laboratory methods and repeated search for the *T. pallidum* and the Donovan body.

It is usually difficult to find the organism in spreads from the open lesion because of the contamination of superimposed infection, but the organism may be grown in a high percentage of cases from the bubo pus aspirated under sterile conditions and grown on agar slants containing defibrinated human or rabbit blood. Skin tests are performed on the forearm by injecting intradermally 0.1 ml. of an antigen prepared from specific organisms. A positive reaction is read within 48 hours and is indicated by an area of 7 mm. of induration. The reaction usually becomes positive from 8 to 25 days after the appearance of the first chancroid. It remains positive for life.

**Treatment.** Until the advent of the antibiotics, the sulfonamides were specific therapy in chancroid. Sulfathiazole was the drug of choice, being administered in divided dosage of two to four grams daily for 7 to 12 days. Penicillin is not effective in the treatment of chancroid, but both streptomycin and aureomycin have been used successfully.

**Prevention.** The key to prevention is cleanliness. The use of soap and water immediately after exposure is practically an absolute preventive. Chancroid, aside from the possibility of a mixed infection, is relatively unimportant from a public health standpoint. Wider dissemination of information, better standards and improved personal hygiene tend to the elimination of this infection. The trend goes downward from 9,400 cases in 1947 to 3,294 in 1954 reported to the state boards of health in 48 states. Cases are now seen but seldom among the better class in private practice; they are largely confined to the public clinics.

## GRANULOMA INGUINALE

Granuloma inguinale is a mildly infectious, granulomatous ulceration caused by the Donovan body. It runs a chronic course with ulceration of the skin and enlargement of the affected lymph nodes. The term is misleading since the disease is by no means confined to the groin, nor is it always contracted in venery.

The disease was first reported by McLeod from India in 1882, and in the United States by Grinden in 1913. Corbus and Harris in 1908 reported three cases of erosive and gangrenous balanitis which were sufficiently characteristic to be considered the fourth venereal disease. Formerly it was believed to be more or less restricted to tropical regions, but it is now known to be rather widely distributed and increasingly prevalent in both northern and southern sections of the United States.

The period of incubation is not well defined, but probably varies from 8 days to 12 weeks. The initial lesion appears as a papule, vesicle or nodule which in a short time ulcerates and may be mistaken for a chancre or chancroid. The lesion usually occurs on the genitals, in the groin and often on the pubic and anal regions.

The ulceration extends by invasion of the surrounding tissues or by autoinoculations. The ulcers are usually moist and have a characteristic disagreeable odor; they are painless and may persist for years without manifesting any tendency to spontaneous healing. The draining lymph glands are involved and suppurate.

Diagnosis may be made upon the classical clinical picture of the exuberant velvety red, velvety tufts of granulation tissue. This diagnosis can be confirmed by smears and biopsy, the tissue in the former being stained with hematoxylin and eosin and in the latter with Dieterle's silver technic to search for the Donovan bodies which are round, rod-like, and grouped within and without large mononuclear endothelial cells. These Donovan bodies are said to be pathognomonic of granuloma inguinale (Greenblatt 1943, 1947; Dienst and others, 1949; Clarke, 1947).

Streptomycin, aureomycin and chloromycetin have been found to be effective in the treatment of this condition.

The differential diagnosis from chancroid depends upon the presence of the Treponema bacillus and a positive intradermal reaction. The chancre of syphilis is distinguished by spirochetes on darkfield illumination, and so on.

## LYMPHOGRANULOMA VENEREUM

(*Nicolas-Durand-Favre's Disease*)

Lymphogranuloma venereum is a subacute inguinal adenitis of venereal origin due to a filtrable virus. It is distinct from and not to be confused with granuloma inguinale. Lymphogranuloma venereum has an incubation period of from 5 to 21 days. There may be a primary lesion which is usually evanescent, but the infection is characterized by involvement of the drainage lymph nodes. The adenitis of lymphogranuloma venereum is characteristic. The nodes of a chain become fused together in a large mass which may reach half the size of a fist, and then the process breaks down with multiple fistulous openings. There may be systemic symptoms of malaise, loss of appetite, loss of weight, rheumatic symptoms, eruptions on the skin and some febrile reaction. In the female the picture is somewhat

different owing to the fact that most of the lymph channels running from the groin and vulva drain into the nodes around the lower part of the rectum. The filtrable virus causing this infection has been transferred to several lower animals—monkeys, rabbits, white mice and guinea pigs. The disease is by no means rare in America (Koteen, 1945).

Diagnosis is made by means of the Frei test, by biopsy, by auto-inoculation, by the complement-fixation test, and by the so-called inverted Frei test. The most important test, although it is not specific in routine diagnosis, is the Frei test. The most reliable and best standardized antigen for this test is the infected yolk of chick embryo (Lygranum) along with control material from uninfected yolk. The Frei test is performed similarly to the intradermal test for chancroid and is read in a similar manner. The same antigen used for the skin test may be utilized for a serologic complement-fixation test. Although this test is not generally in vogue, it is said to be a very sensitive test and of much value in early diagnosis as well as of value in judging the efficacy of treatment. The inverted Frei test is the use of pus aspirated from a bubo to form an antigen for injection into a known case of lymphogranuloma venereum. If the original case was lymphogranuloma venereum, a positive reaction will be evoked. Treatment varies with the stage: the tetracyclines in the earlier phases and chloramphenicol or sulfadiazine continued for 30 or more days after the discharges subside.

### VENEREAL DISEASE CONTROL

The same principles apply to the prevention of the venereal diseases as to the prevention of other communicable diseases. The fight against venereal diseases, however, is especially complicated and difficult because of the close association with prostitution, the problems of sex and morality. Measures that have helped the decline of tuberculosis and other infections are of less import with the venereal diseases, because they do not stop the basic urge which underlies their occurrence. There are three primitive appetites of man: hunger, thirst and the sexual appetite (libido). The first two persist throughout life; the last blooms at puberty, grows stronger during adolescence and wanes with age. Any program for the control of the venereal diseases must take into account the fact that we are dealing with a primal, impulsive and natural passion which is the greatest force for social good, when used in accordance with the laws of nature, but may result in dire consequences when these laws are transgressed. The venereal diseases are among the most widespread and universal of all human ills, and enter more largely into the marring of domestic happiness than any other disease known to man. The difficulties of the situation should not deter the health officer and all others who labor for social betterment. Successful control depends upon sympathetic support of practicing physicians, and persistent prating by health authorities, as well as a better understanding of the problem by the general public.

The general attitude toward the venereal diseases is often inconsistent. There is a natural aversion toward these afflictions, yet the principles for the control of syphilis and gonorrhea differ in no wise from those used in the control of communicable diseases in general although their application is somewhat special and more difficult. Control is bound to be ineffective as long as venereal diseases are regarded

punishment for sin. The immediate problem is the prevention of further spread of the infection. A person afflicted with a venereal disease should be treated in the same humane spirit that actuates in other diseases. The victim and/or culprit need not only sympathy, but even sympathy. Furthermore, the interests of the community require that the patient be accorded effective care and treatment. The usual attitude may well startle us when we consider that some hospitals even now refuse to take a case of syphilis or gonorrhea during the acute stages, when these diseases are especially communicable.

The attitude toward the venereal diseases is well illustrated by the changing views concerning syphilis. It was first regarded as a supernatural visitation, like other plagues. Then the disease was belittled and its seriousness not recognized nor realized—the smart set even regarded it as a distinction. Afterward it came to be regarded as something shameful. This attitude persisted for three centuries and still prevails. It encouraged concealment, promoted spread and retarded progress. Recently, it has been classed with communicable infections and regarded objectively. Nevertheless, a program for the control of the venereal diseases can be effective only if the peculiarities of this problem are taken into account.

**Laws and Regulations.** The laws and regulations which have been enacted to facilitate the control of venereal diseases are further proof of the peculiarity of these communicable diseases as compared with others in the public health program. In addition to premarital and prenatal examination laws, there is a great variety of complicated legal provisions concerning the reporting, management and control of these diseases. Some of the states require that morbidity reports be sent directly to the state department of health; others specify reports shall be forwarded to the local health officer of a jurisdiction of a particular size. Some states require the name of the patient to be reported, others have this requirement only if treatment is prematurely discontinued. A few states allow a "key" number or the initials to be used in lieu of the name. Some regulations require the name and address of the "source" of the patient's infection. It is illegal in certain states to infect another person. In others the citizen is called upon to report to the health authority the name of anyone who may be spreading a venereal disease. Druggists in some states are required to report all prescriptions relating to the treatment of venereal disease. According to some laws, the infected may not move from one place to another, may not travel from one state to another without the permission of the health officer. In several states it is illegal for a teacher to be employed who has or ever has had a venereal disease. In some, parents are held responsible for the treatment and control of minors.

It cannot be denied that the principles behind most of these laws are important factors in the control of venereal diseases, nor that some of these laws are important aids in control. Nevertheless, the venereal diseases cannot be controlled by legislation. Control of gonorrhea, syphilis and the other venereal diseases is a problem of diagnosis and treatment and of discovering how to persuade people to suspect infection. Much more will be gained by the venereal disease control officer without a badge and without a club, without authority and powers, except in a few instances. The most effective laws are those which serve actually to protect the population and which permit local departments of health to give suitable service to the physician, the clinic, and the institutions which diagnose and treat these diseases.

**Notification.** It is not possible to control any communicable disease, especially one that is pandemic, such as syphilis or gonorrhea, without a knowledge of the cases and deaths. It is perhaps even more important to collect morbidity statistics of syphilis than it is of smallpox. Compulsory methods are only partly successful against syphilis than it is of smallpox. Compulsory methods are only partly successful against syphilis than it is of smallpox. A little may be expected from voluntary registration. The public health registration of ophthalmia neonatorum is successful because this form of gonorrhea is so apparent and the consequences are so immediate and serious.

For the year ended June 30, 1949, 296,500 cases of syphilis, 342,900 cases of gonorrhea, and 7,400 cases of chancroid were reported to state and territorial boards of health in the United States (U. S. Public Health Service, 1949).

Table 4-2. Cases of venereal diseases reported to state and territorial boards of health, July 1 to June 30, 1946-1954.\* Figures indicate thousands of cases

Syphilis					
Year	Primary and Secondary	Early Latent	Late and Late Latent	Congenital	Not Stated
1946	96.2	110.7	129.1	14.2	20.8
1947	107.8	111.5	124.6	14.1	24.5
1948	81.4	101.4	125.9	14.5	22.7
1949	54.9	88.0	123.8	15.7	14.1
1950	32.8	68.4	115.4	15.1	6.9
1951	18.7	55.7	110.9	14.6	8.2
1952	12.4	40.6	105.4	10.4	7.7
1953	9.8	33.8	104.0	9.0	6.2
1954 <sup>1</sup>	7.9	25.8	96.0	7.6	4.5

Other Venereal Diseases				
Year	Gonorrhea	Chancroid <sup>2</sup>	Granuloma Inguinale	Lympho-granuloma Venereum
1946	368.0	7.1	2.2	2.6
1947	400.6	9.0	2.4	2.7
1948	363.0	8.6	2.3	2.5
1949	331.7	7.2	2.7	2.1
1950	304.0	5.7	2.0	1.6
1951	270.5	4.7	1.6	1.3
1952	245.6	3.8	1.1	1.2
1953	243.8	3.5	0.8	1.1
1954 <sup>1</sup>	239.7	3.3	0.6	0.9

\* VD Fact Sheet, December, 1954, page 10.  
<sup>1</sup> Estimated.  
<sup>2</sup> Includes some unspecified "Other Venereal Diseases."

The details of notification and reporting systems, and the collection and analysis of statistical data may be found in standard reference papers, pamphlets and books (Nelson and Crain, 1938; Nelson, 1942; American Public Health Association, 1955).

**Fundamental Factors in Control.** At any time the status of disease control in a community will depend upon the relationship between the causative agent of disease, the human host, and the environment. An appreciation of the relations

of these factors is essential for an understanding of incidence and prevalence, for effective case finding, and other intelligently directed venereal disease control efforts (Clark, 1948).

**THE AGENTS.** The biologic requirements of the various agents explain why the venereal diseases are diseases of intimate contact. These organisms require moisture to live, have low resistance outside the human host, and usually die when dry. Thus they can live only in those areas which are constantly moist.

**THE HOST.** The habits and customs of the population determine whether or not the biologic requirements of these organisms are going to be met in a manner which facilitates the spread and perpetuation of the diseases.

**THE ENVIRONMENT.** As a basic factor in the occurrence and distribution of disease, this term is used in its broadest sense which includes physical environment, social and economic environment and biologic environment. Physical environment—that is, weather, climate, etc.—has considerable effect on the amount of clothing, the proximity of contact, and the amount of moisture exchanged from person to person. The social and economic environment—including income, housing, education, medical care and availability, cost and use of medical services and provision of control measures—determine to a considerable extent the occurrence and distribution of the venereal diseases in a particular community.

Thus, the biologic characteristics of these agent-host relationships and the nature of the environment make it impossible to apply the usual control measures of communicable disease such as: (1) the elimination of the organisms in the physical environment, such as can be done in diseases not spread by personal contact; (2) the elimination of intimate contact; it may be possible to reduce contact, but the elimination of the type of contact which spreads venereal disease is absolutely impossible; (3) immunization; and (4) the practice of mass quarantine. Therefore, in view of these characteristics, our efforts in venereal disease control must be directed toward methods that will reduce *effective* exposure to the specific micro-organisms. There are at least four of these: (1) reduction of total exposure by decreasing promiscuity; which includes the suppression of prostitution, a function of law enforcement, and thoroughgoing sex education; (2) prophylaxis; (3) maintenance of adequate treatment and post-treatment requirements among discovered infections (case holding); (4) a reduction of periods of infectiousness by earlier recognition of undiscovered infections; this means *case finding*.

**Reduction of Total Exposures.** It is a sound policy to insist that gonorrhea and syphilis are communicable diseases dangerous to the public health, but no matter how strongly this is argued, the fact cannot be escaped that they are spread by *promiscuous* sexual intercourse. There can be no doubt that the spread of venereal disease is enhanced by multiple sexual exposures to multiple partners. The converse is also true. The fewer the exposures, the smaller the probability of spread of infections. This complex problem is a basic one in venereal disease control. Responsibility for its solution is divided among many agencies of varying interest such as health departments, sociologists, the police, educators, social hygienists, correctional agencies, and the like. Each of these agencies, working along diverse lines, has a contribution to make to the ultimate control of the venereal diseases.

Venereal disease control is seriously complicated by the difficult problem of prostitution, the prostitute being the most efficiently promiscuous part of the popu-

lation. Any measures taken for the prevention of venereal diseases which do not include some method for handling the problem of prostitution are doomed in advance to failure, since they will ignore the main square and root of these diseases. The following four ways of dealing with prostitution have been attempted: (1) *laissez-faire*, (2) suppression, (3) regulation and (4) the systematic treatment of all infected.

A policy of noninterference satisfies no one. Despite the difficulties and complexities of the situation, prostitution must be met with determined but humane action to lessen its extent and diminish its dangers. Prostitution must at least be made *difficult* and *distant*, for the extent of the patronage is in direct ratio to its accessibility. The total elimination of prostitution is beyond the dream of even the theoretical reformer. Any program must take into account the fact that many prostitutes are mental defectives and often need treatment and guidance rather than punishment. Suppression does not suppress. Virtue cannot be secured by legislation. Repressive measures drive the traffic into obscurity and reduce it materially. Vice is not flaunted in public but is driven into corners where seekers will find it, but where it will not entice the innocent and unwary. Between the flagrant evil of segregation and the imperfections of suppression, the choice is with the latter.

Regulation of prostitution by means of medical inspection and licensure has proven a failure wherever tried. Regulation implies the absence of any expectation of male self-restraint; it is society's tacit assent to laxity. Regulation fails because it makes vice easy, gives a false sense of security, and does not reach clandestine prostitution. The systematic treatment of all infected persons, especially of prostitutes, would go far toward diminishing the prevalence of venereal diseases. To accomplish this, we must have adequate and inviting facilities for treatment.

**Prophylaxis.** The object of this procedure is to diminish the *effectiveness* of exposure to the specific organisms through sexual intercourse. It is accomplished by the imposition of an effective barrier or by the use of substances which kill the organisms at the time of or following entry into the human host. There are three types of prophylaxis, the effectiveness being based upon the biologic characteristics of the organisms and certain characteristics of the host-agent relationship. They are chemotherapeutic, chemical and mechanical, each of which has been proved effective in the experimental animal. Military experience during World War II and laboratory experiments based upon it did not provide absolute evidence of the effectiveness of chemical prophylaxis. Chemotherapeutic prophylaxis, on the other hand, with the advent of the new antibiotics, shows considerable promise, recent experiments indicating a high degree of effectiveness. Experiences with oral penicillin prophylaxis have resulted in a reduction of as much as 90 per cent in the incidence of gonococcal infection under controlled use. The importance of this procedure in masking syphilis infection has not been established.

Many authorities believe that the use of the condom, that is, mechanical prophylaxis, is the surest protection against venereal infection, provided it is intact and is used properly. It should be employed at the very beginning of sex play. It does not, of course, protect against extragenital infection. It should be remembered that whatever type of prophylaxis is used, the use of soap and water should not be disregarded.

**Maintenance of Treatment and Post-Treatment Requirements Among Discovered Infections.** In any schedule of treatment requiring more than one visit for treatment or post-treatment examination, case-holding is of paramount importance. Case-holding begins with the patient's first medical contact. The informed patient cooperates; the confused or perplexed patient fails to carry out treatment and post-treatment examination schedules. On the other hand, the most completely informed patient may be expected to neglect treatment and post-treatment examination in the face of rough or discourteous handling, lack of privacy or poor technics which cause pain. Both the control of the discovered case and the discovery of related new cases depend upon the patient's understanding of the illness and its implications since it is the patient who will lead to many of the undiscovered cases. It is upon the patient that we depend for the name and location of his contacts. It is the physician's responsibility to explain the disease to each patient in understandable terms: the reason for taking treatment and for post-treatment examination; his outlook with and without treatment and his potentialities for cure.

Present information indicates that modern antibiotic therapy can accomplish in days what was previously accomplished in months or even years. This fact has greatly decreased the case-holding problem during the treatment period but it increases the importance of post-treatment observation. Penicillin has been found to be effective in every stage of syphilis in which its effects can be measured. Therefore, in spite of the fact that it will be years before the ultimate effectiveness of this agent is completely established, patients treated by the present methods have nothing to fear provided they remain under observation for the advised post-treatment period. At the present time (Oct. 1955) antibiotics are effective in the treatment of each of the venereal diseases. Which antibiotic will prove ultimately to be superior awaits further experience and more extensive trials of the newer forms. The evidence today is that penicillin is not excelled by any drug in its efficacy in practically all the manifestations of syphilis.

**Reduction of Periods of Infectiousness by Early Recognition.** The great volume of undiscovered infections is largely responsible for the perpetuation of these diseases. Case-finding procedures planned with intelligent case-holding objectives in view are the basic fundamentals of venereal disease control. Case-finding should not be an objective in itself. It should lead to a better understanding of incidence and prevalence, to protection of the public health and promotion of the public safety, and to adequate treatment of the infected. The case-finding methods now in use are four: (1) a high index of suspicion and judicious use of diagnostic measures in physicians' offices, hospitals and health departments; (2) screening processes, the process whereby physical and/or laboratory examinations for the presence of venereal disease are given an individual because he is a member of a group, all or most of whom are to be examined because they belong to that group (premarital, prenatal, employment, etc.); (3) public information—planned use of mass information media such as newspapers, radio, posters, pamphlets, to disseminate facts regarding the nature of the diseases (transmission, symptoms, consequences, availability of diagnosis and treatment)—in order to induce individuals to seek examinations of their own accord; (4) contact investigation.

**HIGH INDEX OF SUSPICION.** The importance of the high index of suspicion in case-finding is shown by the fact that during the last three months of 1954 physi-

cians reported approximately one sixth of the cases of gonorrhea, 48 per cent of the cases of primary and secondary syphilis, 46 per cent of early latent, 43 per cent of late and late latent syphilis and 39 per cent of congenital syphilis. Reports from physicians and hospitals in various parts of the country before 1945 showed venereal disease rates ranging from 2.7 per cent to 48 per cent of the patients who come to the offices and hospitals (Clark, 1945). Recent data on such rates are not available.

**SCREEN EXAMINATIONS.** Results of the examinations of the population based on social, economic or occupational groupings depend upon the individual group under study. These range from 0.2 per cent among white female college students to 4 per cent among Negro male college students; from 2.5 per cent among Negro high school students to 5.8 per cent among department store employees (Clark, 1945). Thus, there is a great variety of outcomes of such examinations, depending upon the individual groups under observation.

**PUBLIC INFORMATION.** Intelligent public understanding of the nature and characteristics of the venereal diseases and the objectives of the control program is absolutely essential to gain public support of the program and to ensure effective use of the diagnostic and treatment facilities provided in the community. Effective public education both accelerates case-finding and improves case-holding. It should also serve in some measure to reduce exposure and to encourage prophylaxis against infection. Measurements of the results of the public information program in the venereal diseases is expressed usually in terms of number of diagnostic observations, the number of new cases found, the number of old cases returned to observation to treatment, and the number of cases of early syphilis brought under observation. Great care should be exercised to give the public facts without overdramatization and exaggeration. It is likely that some of the undesirable legal statutes in some states today are the result of overexaggeration which led to hasty and ill-advised public response.

**CONTACT INVESTIGATION.** The choice of a case finding method will depend upon prevailing infection rates in the community and available facilities (Clark, 1945). Contact investigation is the most direct epidemiologic approach and offers the best opportunity for discovering early infectious cases. Contact investigation starts with the infected patient and proceeds cautiously into the home or the community where that person may have acquired the disease and where he might have transmitted the disease to others. It seeks to discover infection among all of his intimate contacts as early as possible and to discover infection previously overlooked or dismissed as trivial. The ultimate value of contact investigation is in direct proportion to the length of time by which the infectious period is shortened in those contacts who have syphilis. Thus, accomplishment is not measured by the number of contacts examined and treated but by the degree of success in materially shortening the contact's period of infectiousness.

The process of contact investigation begins when the patient comes into the office or clinic. This patient, or the potential patient, has vital information that is needed for success in venereal disease control. Whether or not this patient divulges this information depends upon his attitude. His attitude in turn depends upon how he is treated by clerks, nurses, investigators and the doctor.

The literature abounds with reports of contact investigation in public and private clinics on local, state and national levels. In spite of some differences in detail,

agree that: (1) persuasion is superior to compulsion; (2) success depends upon the interview with the patient; and (3) a successful interview depends upon the patient's understanding of the situation as it is concerned with him and his.

In the approach to the patient or to the contact named by a patient, one of the most important things to be remembered is the desirability of not differentiating between source and spread contacts. The expression "source of infection" carries the implication of accusation and should be avoided purposely both in the approach to the patient and to his contact. Fixing the blame is unimportant since each infection is a potential source of another one. The patient, when asked "Where do you think you got this?" or "Who gave you this?" thinks in terms of his most recent exposure or the consort he dislikes or suspects or about whom he has heard rumors. He thinks in terms of a single individual or a single exposure since (presumably) he has been informed prior to this questioning that the disease is spread from one person to another person through intimate contact. He is asked to make a decision which, because of the variation in incubation period, is difficult or even impossible for the trained physician. This question also allows the patient to maintain the concept of being wronged or of having wronged someone else. The question, "Where did you get it?", indicates only one person and ignores those exposed to the patient's own infection. It does not answer the basic epidemiologic question, "Who has been exposed to syphilis?", nor does it allow maximum epidemiologic attack. If further transmission of the disease is to be arrested, information must be sought concerning all sexual contact over intervals selected to include both the stage of active communicability and incubation period of the disease. These intervals have been variously defined but, in general, examination should be made of all contacts of the three-month period prior to the appearance of a chancre or the four to six months prior to the onset of secondary manifestations. The examination of contacts (other than marital and family contacts) of patients with syphilis of more than 12-month duration contributes little to the control of the disease. Time magnifies the difficulty in finding them and, when found, their period of communicability has already been interrupted by the natural course of the disease.

The married patient presents the first vital problem, that of the interpretation of the diagnosis to the spouse. The emotional reaction on the part of the patient may be one of self-condemnation or spouse-accusation. In either event the patient must be convinced of the necessity for examination of the marital partner. Although it is more desirable for the patient to assume the responsibility of telling the marital partner, valuable assistance can be rendered the patient by a discussion of methods of communicating the information. The decision of what to do under this circumstance will depend upon the degree of mutual understanding that exists between the patient and the spouse and the available facilities of the clinic or office to carry out the most advantageous approach.

In contact investigation, attention is focused primarily upon the patient. The patient is the key to success. Direct questioning as to sexual intimates should follow careful explanation of the disease and adequate consideration of the patient's immediate problem such as telling the family or interpretation to the marital partner. Names of extramarital contacts are readily obtained when properly sought. The "named" contact can be persuaded to submit to examination if the situation is adequately explained.

**Venereal Disease Control in 1955.** In spite of the advent of "miracle-working" antibiotics and in spite of the considerable progress that has been made in venereal disease control over the past 15 years, these diseases, particularly syphilis and gonorrhea, are still public health problems of the first magnitude. The present wave of optimism which pervades medical and public health circles does not seem to be entirely warranted at this time (Clark, 1950) (V. D. Control Today, 1955).

In 1932, Dr. Thomas Parran stated "Syphilis can never be controlled while more than one half of the cases are not recognized for more than a year after onset. There has been indeed an encouraging decline in the number of cases of primary and secondary syphilis reported by states and territories from 1946 to 1955 and less marked declines in latent, late and congenital syphilis. In late 1954 slight rise of syphilis or gonorrhea were noted in 43 states. The diagnosis of early latent, late and late latent syphilis means the diagnosis of cases which were not recognized during the first year or, indeed, the first several years of infection. These represent our failures in case-finding at a most critical time in the course of the disease. The number of cases of early latent syphilis reported each year exceeds those of primary and secondary syphilis. Furthermore, approximately 100,000 late and late latent and 8,000 cases of congenital syphilis are reported each year. These must be added to our failures. It is an old epidemiologic principle that successful control of communicable disease depends upon the recognition and the elimination of sources of infection. We are still missing, every year, more than we recognize. Thus, we must maintain or double our efforts rather than decrease them if we are to expect the control of these diseases in the future.

## CONTAGIOUS DISEASES UNCLASSIFIED AS TO PRINCIPAL MODE OF SPREAD

### ACUTE POLIOMYELITIS

(*Infantile Paralysis*)

HOWARD A. HOWE, M.D.

Infantile paralysis is an acute infectious disease due to a specific virus. The common name is unfortunate in as much as the disease is by no means limited to infants nor is paralysis a necessary characteristic. The virus may invade the central nervous system where it affects principally the lower motor neurones in the anterior horns of the gray matter of the spinal cord, hence the name anterior poliomyelitis. Far more commonly, however, the virus sets up a benign infection in the alimentary tract, unaccompanied by signs of central nervous system involvement. The constitutional symptoms produced by the virus are protean and of variable intensity. The identifying manifestation of central nervous system invasion is weakness or flaccid paralysis of muscles or muscle groups, developing irregularly and reaching a maximum in the course of a few hours or days. If this paralysis is not incompatible with continuation of life, there ensues a period of recovery proceeding to a maximum restoration of function in the course of months or up to a year or more. In a varying proportion of patients there remains some degree of permanent crippling.

**History.** Epidemic poliomyelitis appears to be a phenomenon of the twentieth century in virtually all countries of the North and South Temperate Zones. The paralytic disease, however, was recognized much earlier, and the German physician Heine is usually credited with having differentiated it in 1840 from other diseases of the central nervous system. However, at almost the same time (1843), Collier described a malady which he called "teething paralysis" in a small group of children under two years of age in Louisiana.

During the next 40 years there were numerous accounts of paralytic cases, and the concept of infectiousness gradually emerged, but the first evidence of epidemicity came from Sweden in 1881 and 1887, where small outbreaks were described by Bergenholz and Medin. The name of Medin has since become linked with that of Heine in the annals of this disease. Caverly followed in 1894 with description of an outbreak in Vermont comprising 132 cases, the largest then recorded. From that time epidemics involving larger numbers of people have been reported with increasing frequency. It is doubtful whether this circumstance can be accounted for solely by increased recognition of the disease, although this has certainly resulted from the rapidly expanding consciousness of infectious diseases.

No account of the history of poliomyelitis can be completed without reference to Wickman (1913), whose epidemiological studies of the Swedish epidemic of 1905 laid the groundwork for modern thinking on this subject. Wickman was fortunate in being able to observe the spread of poliomyelitis through several small, relatively isolated rural communities. Although totally ignorant of the causative

gent, he was able to establish chains of transmission not only through contact with frank paralytic cases, but also to postulate the existence of numerous subclinical or symptomatic infections. Modern technics have corroborated and strengthened Vickman's conclusion, as have the epidemiological studies of Frost (1941) during 1910-1912, of Lavinder, Freeman and Frost (1918) on the historic epidemic of 1916 in New York City, as well as those of Aycock, and many other investigators.

**Etiology.** Following the successful reproduction of the disease in monkeys, and the identification of the infectious agent as a virus by Landsteiner and Popper in 1909, it was possible for Kling and his associates to demonstrate its presence in the stools and nasopharyngeal secretions of persons sick with the disease and some of those in contact with them. This work was confirmed and extended by Flexner and his co-workers. The experimental disease in the rhesus monkey was fully described, and this provided a means of identifying the virus of poliomyelitis and differentiating it from other viruses. Monkeys paralyzed following inoculation were found to be solidly immune to a second paralytic attack induced by the same virus material, but it was not entirely clear at that time whether the presence of neutralizing antibody in the blood serum of the convalescent was responsible for this. In 1939, Armstrong was successful in adapting the Lansing strain of poliomyelitis to cotton rats and mice. This provided a valuable new tool for experimental research. It led to the development of a technic by which the serum neutralization test carried out in mice could be used quantitatively for determining quite precisely the distribution and level of antibody against this type of poliomyelitis virus in experimental animals and in human populations. It thus made possible the basic work on the immune mechanisms of poliomyelitis which were of great importance in showing the way toward control by vaccination. At the same time it provided the tools for the first large scale serum antibody surveys in human populations. Of crucial importance was the discovery by Enders and others (1949) that poliomyelitis virus could be grown in cultures derived from various human embryonic organs and from monkey kidney and testis. This provided a medium more economical and efficient than animal inoculation for the isolation of virus and the measurement of antibody. More importantly, it could be adapted to the large scale production of poliomyelitis virus in high titer and relatively free from extraneous material, hence eminently suited for use as a vaccine.

With the observation that the chimpanzee is highly susceptible to alimentary and central nervous system infection after oral ingestion of the virus of poliomyelitis, Howe and Bodian (1941) provided another experimental animal which is closest to man in its clinical reaction to this disease.

Evidence for the existence of distinct antigenic types among poliomyelitis viruses was first shown experimentally by Burnet and McNamara in 1931. These observations were confirmed and extended with improved technical methods and it has recently been shown that there are at least three distinct antigenic types, which are widely distributed (Bodian and others, 1949; Kessel and Pait, 1950; Committee on Typing of the N.F.I.P., 1951). Animals immunized with one virus type are immune to a challenge inoculation with the homologous type but are still susceptible to infection with the other two (heterologous types).

**Portal of Entry.** In human infections with poliomyelitis, the virus is localized in the walls of the nasopharynx, the intestinal tract and certain portions of the central nervous system (Sabin and Ward, 1941). Since the virus has on numerous occasions been demonstrated in the alimentary tract some days before there was evidence of nervous involvement, and is frequently found in this site without any evidence of central nervous system invasion, it seems clear that the site of initial virus growth is in the alimentary tract. Virus has not been demonstrated in the olfactory mucosa or the olfactory bulbs of fatal human cases. This points strongly

to the mouth as the portal of entry, although it does not entirely rule out the nasopharyngeal passages as an accessory portal to the tissues of initial localization in the alimentary tract.

**Incubation Period.** Casey (1942a) collected a series of 37 cases which were presumed to have followed a single known exposure. The incubation period varied from 5 to 35 days, with the average at 12.2 days. This is in conformity with the incubation periods observed in chimpanzees following oral inoculation of virus; these ranged from 7 to 31 days, with an average of 15 days. Four days is the shortest incubation period ordinarily observed in monkeys following direct intracerebral inoculation. This would indicate that supposed incubation periods in man of less than four days should probably be regarded as erroneous.

**Pathogenesis.** There has been accumulated a great body of experimental evidence showing that the virus may spread along the axones of peripheral nerves and, having reached the central nervous system, continues to progress along nerve fiber pathways (Howe and Bodian, 1942). However, the relatively recent finding, both in chimpanzees and human beings, of a transient viremia during the preparalytic phase of the disease points to the blood stream as an important potential route to the CNS from the alimentary tract (Bodian, 1952a; Bodian and Paffenbarger, 1952; Horstmann, 1952; Horstmann and others, 1954). The isolation of virus from tonsils, Peyer's patches, cervical and mesenteric lymph nodes of chimpanzees before the onset of viremia (Bodian, 1955) recalls earlier descriptions of a lymphatic phase in man.

The virus attacks and either damages or destroys certain types of nerve cells preferentially. Those most seriously affected are the anterior horn cells of the spinal cord, but in severe disease the cells of the intermediate gray (this includes the spinal centers of the sympathetic nervous system) and even the posterior horn and dorsal root ganglia may be attacked. In the brain stem the scattered cells of the reticular formation, the vestibulo-cerebellar complex, the thalamus and the motor cortex are also vulnerable. Conspicuously spared is the balance of the cortex. There is no acceptable evidence that virus invades or proliferates in muscle, although it grows readily in tissue cultures of human embryonic muscle.

**Clinical Manifestation.** It is generally recognized that many poliomyelitic infections produce no symptoms at all, or that they may be associated with a nonspecific syndrome consisting of fever, malaise, drowsiness, headache, nausea, vomiting, constipation, or sore throat in various combinations. These cannot with assurance be recognized as poliomyelitis, even in the presence of an epidemic setting, unless virus is isolated. Patients who present muscle pains and stiffness of the neck or back, in addition to the previously mentioned signs and symptoms, and who also show an increase in leukocytes and protein in the spinal fluid as an indication of central nervous system involvement, may be diagnosed as having nonparalytic poliomyelitis with considerable assurance, particularly if these symptoms occur in individuals associated with frank paralytic cases. However, the distinction of the nonparalytic patients from those showing weakness and flaccid paralysis of voluntary muscle is entirely one of degree, since in both types the central nervous system is invaded. Patients with fever who complain of various discomforts but who have normal spinal fluid may be regarded only in an epidemic setting as having "abortive" or presumptive poliomyelitis.

While the clinical picture of paralytic poliomyelitis involving the central nervous system is dominated by the flaccid paralysis resulting from lower motor neuron damage or destruction, ataxia and incoordination probably secondary to brain stem invasion, have also been noted. Painful spasms of unparalyzed muscles also occur. The mechanism of these latter is obscure, but may be readily rationalized on the basis of damage to the central nervous system. Every degree of destruction

motor cells may be encountered and is reflected in signs which vary from complete and irreversible paralysis to affections so slight that disease can be detected only by the presence of abnormal protein and leukocytes in the spinal fluid.

The Coxsackie viruses have been frequently demonstrated in individuals who are also harboring poliomyelitis virus, and the clinical picture of Coxsackie infection is said on occasion to resemble that of nonparalytic poliomyelitis (Curnen and others, 1949). Similarly, signs of meningeal irritation have not infrequently been associated with the presence of mumps virus (Kilham and others, 1949). These agents, which produce an "aseptic meningitis," can at times be ruled out only by appropriate laboratory procedures (virus isolation and/or complement fixation or neutralization tests).

**Immunity.** Infection with the virus, even though asymptomatic, is followed by the development of complement fixing and neutralizing antibodies in the blood serum. The former are said to decline in titer more rapidly than the latter and thus indicate relatively recent infection, but the evidence is still accumulating on this point. Neutralizing antibody may still be present for three years after infection or possibly even as long as 20 years. Furthermore, the age at which neutralizing antibody is first acquired in the population closely follows that of the paralytic disease (Turner and others, 1950).

Since poliomyelitis is primarily a children's disease and second attacks are extremely rare, it follows also that antibody is somehow connected with immunity. Yet in a given population group, antibody titers extend over a wide range. For example, in a group of 68 young adults, mostly graduate students, Bell (1948) found type II antibody present in high titer (1:100) in 22 per cent, while the majority (41 per cent) had intermediate titers (1:10 to 1:90). An appreciable number (37 per cent) showed low titers (1:2 to 1:9) or else no evidence of antibody at the level of the test, yet these individuals all belonged to an age group in which paralytic rates average no more than 5 per 100,000. This epidemiological evidence indicates that relatively low levels of antibody suffice to insure protection against paralysis, although it has been clearly shown that adult family contacts of cases not infrequently become alimentary virus carriers (Wenner and Tanner, 1948). In recent years these deductions have received ample support from the laboratory and field where it has been possible to more clearly define the quantitative aspects of the relationship between antibody and immunity. The first steps consisted of the demonstration in monkeys that immunity to direct brain inoculation regularly followed vaccination with active or formalin inactivated virus if the quantity used was great enough to induce high levels of serum antibody (Morgan and others, 1947; Morgan, 1948; 1949). Later it became apparent in cynomolgus monkeys that much less antibody protected against paralysis following introduction of virus by peripheral routes such as intramuscular inoculation or feeding (Bodian, 1952b). In the chimpanzee, it was shown that serum antibody passively introduced did not prevent alimentary infection and that relatively low levels were associated with the absence of viremia and paralysis (Bodian, 1953). Furthermore, the experiments of Hammon and others (1953) indicated that in man barely detectable circulating antibody introduced in gamma globulin could occasionally prevent paralysis.

Meanwhile, the understanding of poliomyelitis was considerably advanced by the discovery that three immunological types of virus existed (Bodian and others, 1949; Kessel and Pait, 1950) and that these were widely distributed throughout the world (Committee on Typing, 1951). In the laboratory, at least, no one of these three conferred cross immunity against the others. It also seems highly probable from the work of Bodian in 1951 that second attacks of paralytic poliomyelitis in human beings, though rare, are due to unrelated types. All of this information, accumulating like a flood, finally led to the demonstration that relatively low levels

of antibody induced in human beings with trivalent formalin inactivated vaccine do in reality protect against paralysis (Evaluation of the 1954 Poliomyelitis Vaccine Trials).

**Provoking Factors.** Explanation has long been sought for the fact that most humans acquire their immunity to poliomyelitis through subclinical infections and nonparalytic attacks. Only the occasional individual has some degree of paralysis. The hypothesis has been advanced that the difference might be the result of some provoking factor which temporarily depressed the resistance of the central nervous system to virus invasion. The idea that disturbances in nutrition might act in this manner has been widely held but has received little support in experimental work. There is also no convincing evidence of the effects of prolonged chilling within ordinary physiological limits. There are, however, four factors which have been associated quite definitely with the occurrence of paralysis, namely, (1) excessive fatigue; (2) oral operations (as tonsillectomy and adenoidectomy); (3) the injection of antigenic materials, such as diphtheria toxoid and pertussis vaccine; and (4) pregnancy.

1. **EXCESSIVE FATIGUE.** This has long been suspected as a provoking factor, but it is only in recent years that controlled observations have been made on humans under the conditions of ordinary life (Russell, 1949). It now seems reasonably clear that the severity of paralysis is not enhanced unless the subject persists in rather violent exercise beyond the time at which signs of central nervous system invasion are demonstrable. In the absence of such signs as stiff neck, stiff back, headache and muscle pains, exercise appears to have no deleterious effect.

2. **ORAL OPERATIONS.** It is known that healthy children carry the virus in their throats and that virus has been demonstrated in tonsils removed by routine operations. In recent years, convincing evidence has accumulated that tonsillectomy and adenoidectomy may serve as provoking factors for paralytic poliomyelitis, particularly the bulbar variety. In 1942, Aycock first reviewed the subject and was able to accumulate many instances from the literature showing that among cases of poliomyelitis with a history of tonsillectomy 60 days prior to onset of paralysis there was a marked concentration of bulbar and bulbo-spinal types within the first 30 days while spinal and nonparalytic cases were randomly distributed over the entire 60-day period. It has been shown (Anderson and others, 1950) that attack rates for bulbar poliomyelitis are 10 times higher among the recently tonsillectomized as compared with the same age group in the general population.

The hypothesis that exposed dental pulp might afford a portal of entry for poliomyelitis virus has received some attention but the recent study of Finn and others (1947) failed to show any significant relationship. There is also evidence that tonsillectomy predisposes to the bulbar form of poliomyelitis at any time during life (Anderson and Rondeau, 1954; Paffenbarger and Wilson, 1955).

3. **INJECTION OF ANTIGENIC MATERIAL.** In recent years evidence has been accumulating to indicate some causal relationship between injections of antigenic materials (especially diphtheria, pertussis, tetanus antigens) and the localization of paralysis in poliomyelitis. This has been reported from England, Australia and the United States (see Korns and others, 1952, for a study in New York State and references to previous observations). It is by no means clear that under ordinary circumstances the total incidence of paralytic disease is increased by such injections and the accounts describing the phenomenon vary considerably in respect to duration and to its correlation with age. In general, there is agreement that the highest incidence of paralysis is recorded within one month after injection of antigens. The phenomenon has been most consistently observed in children under three years of age. The most striking evidence for provocation is found in the frequent localization of paralysis in the spinal cord level of the extremity injected.

Since immunizations are usually given in the arm, this results in a preponderance of arm paralysis, while ordinarily leg paralysis predominates. Primary immunizations with D.P.T. are ordinarily restricted to infants under six months of age, a group in which poliomyelitis incidence is negligible, so that this finding has had little effect on immunization programs other than to indicate the wisdom of deferring selective booster inoculations of older children to periods when poliomyelitis incidence is relatively low.

4. **PREGNANCY.** It has long been suspected that pregnancy predisposes to paralytic poliomyelitis, but this relationship has been more clearly established in recent years by careful epidemiological studies (Anderson and others, 1952; Paffenbarger and Wilson, 1955). For example, the second authors cited above compared the risk of acquiring paralytic poliomyelitis among immediate contacts of cases. They found that in a group of 89 pregnant contacts, 7 per cent developed the disease as compared with 1 per cent of 651 nonpregnant female contacts of comparable ages. Furthermore, the age-adjusted rate for pregnant females (denominator estimated) was double that for nonpregnant females or married males.

**Geographic and Seasonal Distribution.** The records of the World Health Organization and those of the League of Nations before it, indicate that poliomyelitis is world wide in its distribution. At the same time there are many countries in which the disease is known to exist but where it seldom reaches epidemic proportions. These countries almost invariably have a warm or mild climate and populations that live under primitive conditions. They also have insufficient public health organizations and medical care. Frequently the pressing problems of malnutrition, malaria, cholera, dysentery, tuberculosis, parasitic infections and the like obscure the recognition and reporting of cases of poliomyelitis. Despite this, in recent years there have been reports of small outbreaks in such countries as El Salvador, Puerto Rico, Venezuela, Ecuador, Palestine and India. These outbreaks are almost exclusively confined to children under five years of age.

While poliomyelitis is clearly not a new disease in the countries just cited, there is no doubt that awareness of it has increased all over the world. It is by no means certain whether these recent records of epidemics reflect increased recognition and accuracy of reporting, or whether they describe the transition of poliomyelitis from an endemic to an epidemic disease. There is little doubt that the latter phenomenon occurred around the turn of the past century in the countries of the temperate zone.

Reports of poliomyelitis in the Arctic have not been numerous, but it is clear from available information that the disease reaches its greatest epidemicity in these regions. In contrast with the tropics, or even the temperate zones, the virus is absent for considerable periods of years and upon reintroduction may build up high paralytic rates in young and old alike (Peart, 1949).

The propagation and/or transmission of poliomyelitis virus is apparently facilitated during warm weather, although it may take place in subzero temperatures of the Arctic. In the tropics, where small outbreaks may occur during any month of the year, they are probably only the peak variations of a high endemic level. While occasional winter epidemics have taken place in the temperate zone, midsummer and fall are unquestionably the months of highest incidence in these areas. Nevertheless, cases continue to occur throughout the colder months of the year. During years of unusual prevalence, reporting shows a definite upswing of cases as early as spring. This is shown in Table 5-1, retained from the previous editions of this book but still pertinent.

Seasonal variation is somewhat magnified by reporting deficits which were clearly demonstrated by Nelson and Aycock (1944) in a retrospective study of paralytic patients who were known to the Harvard Infantile Paralysis Commission. On searching the records in the communities where the cases had originated, these investiga-

tors found a deficit of 68 per cent in the reporting of paralytic cases which occurred between the months of January and May.

**Prevalence Rates.** Average annual rates based upon reported cases and registered deaths from poliomyelitis are much lower than those recorded for such communicable diseases as measles, scarlet fever and diphtheria, but are similar to those of meningococcus meningitis. The average annual morbidity rates tabulated by Gilliam and others (1949) for the counties of the United States from 1932 to 1946, show 77 per cent of them under 9 per 100,000 while mortality rates averaged between 0.6 and 0.7 per 100,000 in the states of the U. S. Registration Area between 1932 and 1940 (Gilliam, 1948). As might be expected with increased recognition and reporting of this disease in recent years these rates are now somewhat higher.

**Age Selection.** Poliomyelitis is a children's disease the world over, although there are some important minor differences in age selection which throw considerable light on its character. Infants are susceptible at birth and cases do occur during the early months of life, but are rare until after the sixth month, which presumably marks the waning of maternally transferred immunity. Rates range from 25 to 100 per 100,000 for children under 10 years, from 10 to 25 per 100,000 for the next decade of life and are 5 to 10 per 100,000 for those 20 to 30 years of age. At ages above 30 years they are very low. These are, of course, average rates and do not accurately describe any particular epidemic situation, although they clearly show the highest incidence of the disease to be in the youngest age groups. While the predilection of the disease for children has several interpretations, only one seems in conformity with the facts. It is not logical to assume that exposure to the virus is significantly greater in the younger age groups, since all ages live in the same homes. Neither can it be shown that mere physiologic maturity brings a type of nonspecific resistance, for the average age of paralytic patients has been considerably higher in rural areas than in large cities of the same climatic zones. The exclusion of these possibilities leaves the acquisition of specific immunity as the most acceptable explanation of the age selection in poliomyelitis. This is corroborated by the fact that the acquisition of serum antibody against the Lansing type of poliomyelitis virus closely follows the age pattern of the paralytic disease (Turner and others, 1950).

**Changes in Age Selection.** Since the first recognition of poliomyelitis as an epidemic disease, rather striking changes in age selection have taken place. For example, in the United States there has been a consistent reduction in the specific rates for children under five years. This has been noted in relation to deaths since 1910 for the Registration Area of that time by Gilliam (1948), and since 1920 in relation to total reported cases as well as deaths in five northern states by Dauer (1948). At the same time there has been a consistent shift in the incidence of reported cases (a mixture of paralytic and nonparalytic) to older age groups. During the three decades from 1910 to 1940 this involved principally the ages from 5 to 19 years with little change in the rates for adults (Dauer, 1948; Howe, 1948). However, in the period between 1945 and 1951 a further shift to the adult group has been noted (Dauer, 1955) for paralytic cases in the states of Maryland and Massachusetts. Although these rates were far from the magnitude of those observed in children of five to nine years they nevertheless showed a three- to five-fold gain in comparison with the earlier rates of this group. This is to say that in the past decade there has been a shift of paralytic poliomyelitis into relatively older age groups. These changes may not be general for the entire country, but in the areas cited, as well as in a local outbreak in Rochester, Minnesota (Paffenbarger and others, 1954), a further change was noted—a reversal of the usual male preponderance to females in the age groups between 20 and 35 years.

It is interesting to speculate about the significance of this trend. Dauer attributes largely to an increase in the size of families since the 1920's and 30's. During the period of falling birth rate the average size of families decreased. Since it is now clearly clear that the virus is commonly introduced into the family by young children, this circumstance afforded less opportunity for exposure to infection and consequent immunization. Thus, the young parents of the late 40's who were the children of the less fecund decades probably constituted a group inadequately immunized against exposure from their own children (see Bodian and Paffenbarger, 1954 for analysis of the ages of donor and recipient cases during a single outbreak of poliomyelitis). Differences in family size may also in part account for the observation that both cases and antibody appear at later ages in children of higher socioeconomic groups. The observation that type II antibody is more frequently found in members of large families regardless of sociological factors seems to be a case point (Walton and Melnick, 1955).

It must be admitted, however, that other alterations in the life habits of people may also be playing a role in the changing age picture. In the countries which have shown changes in age selection, the past generation has seen marked alteration not only in public and private sanitation, but also an improvement in diet, and some amelioration of housing congestion. However, while these changes have been accompanied by striking reductions in the incidence of enteric disease such as typhoid and dysentery, there has been no reduction in the incidence of clinical poliomyelitis despite the shift in its age selection.

**Frequency of Subclinical Infection.** The ratio of clinical to subclinical cases is indicated by the survey of Collins (1946) which included 20,258 individuals from birth to 24 years of age in 28 cities of the United States. In this group, 11.01 per cent had a history of antecedent paralytic poliomyelitis, including death. Since poliomyelitis incidence is negligible over 25 years of age, these figures indicate that effective immunity had been achieved by the population at the rate of approximately 10 infections to one clinically recognized case. A similar ratio has also been shown by Casey and his co-workers (1950) on the basis of clinical-epidemiologic observations.

Table 5-2. Reported cases of measles and poliomyelitis by age groups—counties of Maryland, 1916-1943 \*

Age Groups	Measles			Poliomyelitis		
	Reported	Cumulative by Age		Reported	Cumulative by Age	
		No.	%		No.	%

TOTAL	99,079			1,185		

\* Figures obtained through the courtesy of Dr. Riley of the Maryland State Dept. of Health.

The ratio of clinically recognizable cases to subclinical immunizing infections is also suggested by a comparison of poliomyelitis and measles, both diseases to which most individuals reaching the twenty-fifth year of life have acquired immunity. In Baltimore, between 1921 and 1944, 119,432 cases of measles were reported among the white population, while during the same period only 898 cases of para-

lytic poliomyelitis were recorded. Similarly, in the rest of the state of Maryland exclusive of Baltimore, from 1916 to 1943 the records show 99,079 cases of measles in all races (which is probably only about 60 per cent of the true number), 1,185 cases of paralytic poliomyelitis with virtually the same age distribution (Table 5-2). It is difficult to escape the inference that there were during this period at least an average of 100 poliomyelitic infections to one reported case of paralytic disease. This, however, as in the Collins' study, represents a cumulative risk and does not describe the situation for any single epidemic.

**Epidemicity.** The term "epidemic" is entirely a relative one when applied to the clinically apparent incidence of poliomyelitis. This may be seen by comparing reported cases of poliomyelitis over a period of 24 years in a large city, such as Baltimore, with two small cities of Maryland. While the disease has been reported every year in Baltimore with periodic upswings, the smaller cities of Hagerstown and Easton have had a much less spectacular, although typical, experience with poliomyelitis.

In Hagerstown and its rural districts, poliomyelitis has been reported only 11 of the years from 1925 to 1948, inclusive. During that time the largest reported outbreak consisted of 11 cases, producing a "rate" of roughly 37 per 100 persons, which is equivalent to those reported in Baltimore at epidemic times. Easton and its environs were conscious of poliomyelitis but four times during this 24-year period. In 1941, two cases were reported, producing a "rate" of 58 per 100. The average annual incidence of the disease was almost identical in the three communities for the 24-year period, thus indicating that each was having about the same experience with poliomyelitis virus as an infectious agent. On the basis of its population and the average paralytic rates for Maryland, such communities as Easton might have produced no more than two cases as an epidemic manifestation.

Many observations attest the fact that immunization becomes less thorough with increasing dispersion of people (Olin, 1951). Thus in all probability the process was less complete in the smaller towns than in the large city although the differences were not great, as is indicated by the fact that the majority of the cases were under 13 years old in all three localities.

It thus becomes apparent that aside from differences in the degree of recognition of the disease the recurring variations in the incidence of poliomyelitis are largely conditioned by the immune status of the population plus the amount of exposure. One is inclined to stress the importance of the former, although heightened risk exposure undoubtedly plays a role in some situations, for example, the increased rates observed in British and American soldiers stationed in Africa, the Middle East, and the South East Asia Theatre during World War II (Paul, 1949). There is every reason to accept the idea of widespread and perhaps continuous dissemination of virus in such countries, since serological surveys in native populations reveal a high prevalence of antibody in children under three years of age.

The unseen portion of any epidemic is by far the larger. It may be visualized on the fact that in the city of Toronto, Canada, Rhodes and his colleagues, in 1947 demonstrated poliomyelitis virus in the sewage one month *before* the first reported case of the season. Similar findings were reported by Gear in 1948 from Johannesburg, South Africa, and in an English village (Goffe and Parfitt, 1955), where virus was still recovered in sewage two months *after* the record of the last case.

Epidemics of poliomyelitis show a frequently recurring pattern of radial spread from a more or less centralized focus. It is a common observation that the center of such an area will be "burned over" and become silent while new cases are occurring on the periphery. The direction of principal progress is unpredictable, as the slowly moving wave of infection engulfs some communities and bypasses others. The disease, however, moves most surely through areas which represent concentrated

people. The rate of progression has not varied appreciably with the advent of mid transit.

**Infectious Period and Contact Transmission.** Laboratory studies have shown virus of poliomyelitis to be present in stools during the acute stages of the analytic disease in such a high percentage of cases that it seems justifiable to consider it a constant concomitant of central nervous system invasion. Within a week of the onset of symptoms the frequency with which virus can be demonstrated in stools is reduced but, nevertheless, virus has been shown to persist in some individuals for as long as 11 to 12 weeks. Child contacts under 5 years of age show very high alimentary infection rates (80 to 100 per cent) which diminish with increasing age (Brown and others, 1954; Casey and others, 1950; Bhatt and others, 1955).

Virus has also been isolated from throat swabs of a high percentage of patients in periods as long as 13 days after the onset of symptoms (Howe and others, 1945; Horstmann and others, 1954). However, it generally disappears before virus is absent from stools. It is probable that the failure to detect virus in the nasopharynx as long as in the stools reflects a real biologic difference, since it is known that antibody may be present in the pharyngeal secretions, although it has not been demonstrated in the stools (Bell, 1948). It is therefore possible that the antibody response following infection clears the pharynx of virus in a relatively short time.

Little is known about the incidence of virus in the stools or pharyngeal secretions prior to the onset of symptoms, although it has been described in the former 17 and 19 days, respectively, before onset. There have also been a few isolations of virus from the nasopharynx four to six days before clinical symptoms were observed. The observations of Bodian and Paffenbarger (1954), Horstman and others (1954), and Bhatt and others (1955) on the appearance of antibody in susceptible family contacts leave little doubt as to the high rate of communicability shown by this disease. Investigation of the virus distribution in the family associates of the patient has amply demonstrated the relative frequency of asymptomatic virus infections of the alimentary tract, while random sampling of the population at epidemic times has suggested a wide distribution of nasopharyngeal and fecal virus carriers, many of whom were not sick (Howe and Bodian, 1947; Brown and others, 1949; Casey and others, 1950; Horstmann and others, 1954).

These studies of the excretion of the virus lead to the conviction that the principal mode of spread of poliomyelitis is by some form of personal contact of susceptible individuals with infected individuals. It brings laboratory confirmation to the original conception of Wickman and is supported by many field investigations made since that time. The frequency with which a clinical case of poliomyelitis can be traced to preceding contact with a *recognized case* varies widely according to many variables, such as completeness of recognition and reporting of cases, definition of contact, definition of case, the skill and objectivity with which the inquiry was conducted, etc. It has recently been shown (Paffenbarger and others, 1954) that a history of contact with a case is about six times more frequent among those who become cases as in the population at large. This is a surprisingly high proportion in view of the fact that so many infections are subclinical. Moreover, the literature is filled with the convincing accounts of isolated episodes in which poliomyelitis has been introduced into remote areas by apparently healthy persons or those in the incipient stage of the disease.

The precise manner in which the virus is transferred from one individual to another is not yet clear. The high infection rate among familial associates and slow propagation of the disease from one household to another suggests that rather intimate conditions of personal association are usually necessary. No one who has watched children at play can doubt that many opportunities exist for direct transfer

of either pharyngeal secretions or feces, not only among the children themselves, also to their adult associates.

Two independent epidemiological studies based upon secondary cases, presumably arising from a single contact with an extrafamilial primary case (C. 1942b; Aycock and Kessel, 1943) suggest that the infectious period is as long as eight days before and 11 days after the onset of symptoms. This was confirmed in 1949 by Silverthorne and other members of the Toronto group. This interval corresponds very closely to that during which the virus is demonstrable in pharyngeal secretions of the patient. The fact that the continued elimination of virus in the stools for a longer period of time has not been connected more frequently with the appearance of late secondary cases constitutes evidence that fecal conveyance by pharyngeal secretions. Both poliomyelitis and measles spread orally and appear to be equally infectious, yet patients with poliomyelitis do not cough or coryza which is so effective as a propagating mechanism in measles. If, however, the virus were even occasionally present in the saliva, it would not be necessary to postulate any other vehicle for its transfer. On the other hand, the parent multiplication of the virus in the alimentary tract and the excretion of large quantities in the feces argues with equal force for this medium of transfer. The concept receives further support from the fact that poliomyelitis behaves seasonally very much as do other enteric infections, such as typhoid and dysentery. However, it is a striking fact that little or no correlation can be demonstrated between the occurrence of poliomyelitis and the level of community sanitation. In spite of the advance which has occurred in the United States in community sanitation and hygiene, there has been no reduction in the incidence of poliomyelitis, although typhoid and dysentery are rapidly disappearing. The possibility exists that different mechanisms of transfer are involved and may operate under certain conditions.

Whatever the mechanism may be, the concept that the principal mode of communication of poliomyelitis is some form of personal contact is no longer just a theory; it should be regarded as an established fact. This concept is adequate to explain all of the known observations on the epidemiological distributions and characteristics of the disease. No other theory so far proposed fits all of the observations equally well. This fact, however, does not preclude the possibility that accidental and indirect routes of spread may be operative under special circumstances.

**Other Possible Routes of Transmission.** Four such possibilities have received attention and have been extensively explored: (1) the existence of an extrahuman reservoir of the virus; (2) the role of flies as vectors; (3) dissemination by contaminated milk; and (4) dissemination by polluted water supplies.

(1) Much speculation and a considerable amount of work have been directed toward discovery of a natural host of the virus other than man (Francis and others, 1948). The search has ranged through many species of animals, birds, and fish, but so far it has been unproductive. Repeated attempts to demonstrate virus in blood-sucking arthropods have been negative. In view of the transient viremia, such efforts might be regarded as insufficient; nevertheless the persistence of poliomyelitis epidemics into cold weather appears to rule out such arthropods as an important vector.

(2) The hypothesis that flies are implicated in transmission is attractive because the season of highest prevalence of the disease, like that of such enteric infections as typhoid and bacillary dysentery, corresponds roughly with the time of year when flies are most numerous. Upon many occasions, investigators have recovered poliomyelitis virus from pools of flies collected in localities where cases of the disease were occurring (Meinick, 1949). For the most part, however, the infected flies were trapped in areas where they had ready access to large quantities of human excrement. Of the five species enumerated, only the housefly (*Musca domestica*)

ely enters human habitations. Quite obviously if flies do play a role in transmission it can only be an accessory one. In several villages extensively treated with DT no difference was noted in the epidemic incidence of poliomyelitis in comparison with neighboring untreated villages despite the fact that dysentery rates were sharply decreased in the former (Paffenbarger and Watt, 1953).

(3) With every outbreak of poliomyelitis which occurs in the United States the possible implication of a common milk supply receives consideration. In the literature prior to 1929 three outbreaks have been attributed to the consumption of raw milk (see page 872). In more recent times there have been a few small focalized epidemics in which contamination of milk was a possible explanation, but the evidence has been vague and entirely circumstantial. In general, with accumulating experience, proof incriminating this medium of dissemination is conspicuous by its absence.

(4) The hypothesis that poliomyelitis is disseminated by polluted water has had many adherents. In considering this matter, a distinction should be made between transmission which may take place around the household by contamination of the private well, spring or container, through improper sanitary arrangements, or the use of a common bathtub, or by community use of the large bathtub known as a swimming pool. Short range and rather direct transmission of the virus in such a manner should be classified as one of the routes of contact infection. To be distinguished from this is the possibility that the pollution of community water supplies may be responsible in some measure occasionally for indirect and widespread exposure of consumers to infection with the virus. The evidence bearing upon this latter hypothesis has been adduced along four lines: recovery of the virus from domestic sewage, attempts to recover the virus from water supplies, effect on the virus of procedures employed in water purification, the epidemiological observations associating occurrence of cases with water distribution systems.

With appreciation of the fact that the virus was commonly present in the feces of infected persons, and that the infection is far more widely distributed in the population than is indicated by the occurrence of paralytic cases alone, it was to be expected that it could be found occasionally in domestic sewage. With the development of sensitive and reliable methods of virus detection by inoculation of monkeys, an extensive series of observations has been made, the results of which were summarized by Melnick (1947), and have been extended by Gear and his associates in Johannesburg, South Africa, as well as by Rhodes and the Toronto, Canada, group. These studies have shown that the virus of poliomyelitis may be recovered with ease during an urban epidemic from raw sewage, and from sewage in the early stages of a treatment process, and less frequently in the effluent of a sewage treatment plant. The occasional finding of virus of poliomyelitis in domestic sewage, along with other pathogens such as *Salmonella*, *Shigella* and tubercle bacilli, is without significance in the transmission of the disease, unless or until it can be shown through what channels the organisms may reach the alimentary tract of human beings. So far the virus has occasionally been traced beyond the effluent of sewage treatment works. That it may occasionally survive conditions which effect natural purification of rivers and lakes and reach the intake of water systems is a theoretic possibility only.

Up to the present, attempts to demonstrate the virus in suspected drinking water supplies are questionable or negative. It is unknown whether if present in raw water at the intake of a surface supply it would be removed by the successive stages of treatment necessary to produce a potable product which is safe by bacteriological standards. However, free residual chlorine as required by good water works practice affords an effective safeguard.

Although a large number of epidemiological studies of the prevalence and dis-

tribution of poliomyelitis have been made during the past half century, up to present no convincing evidence has been presented that pollution of a community water supply was responsible for indirect or widespread exposure of consumer infection with the virus (Maxcy, 1949).

**Control.** No disease creates more apprehension and fear in a community than does poliomyelitis. Public anxiety may find expression in pressure for unjustified restrictions which interfere with community life without having any appreciable effect on the propagation of the disease. Against these pressures the medical profession and health authorities must stand firm. The measures taken must be reasonable in the light of knowledge of the manner in which the disease spreads and in expectation of their effectiveness. In some communities, the existing regulations require practices which are not only ineffective and unwarranted by present knowledge, but which also create problems for patients and families, health officers, doctors and hospitals (Control Measures in Poliomyelitis, 1953).

Efforts should be directed to correctly establish the diagnosis of fatal, paralytic or nonparalytic poliomyelitis. Lumbar punctures should be done wherever warranted, since they provide a valuable diagnostic aid. In making a report to health authorities, the attending physician should classify the case as paralytic or nonparalytic. Physicians must also be alerted to watch for new cases, but it is desirable to keep general publicity at a minimum. If, however, newspaper discussion cannot be averted it can frequently be channeled into a constructive vein; for example, a statement that an average child of 10 years or under has less than one chance in a thousand of being paralyzed—that of those paralyzed, fully 50 per cent recoveries which are complete or virtually so. Also, the knowledge that exposure is inevitable sooner or later is more often comforting than frightening.

Certain control measures can be based upon a realistic interpretation of epidemiological characteristics of poliomyelitis. While little general importance apparently attaches to common media such as food and drink (and to stretch the point a little, one might also include swimming pools), the possibility of their being implicated under special circumstances should never be ignored. Since some remote or intimate type of personal contact appears to be the most probable mode by which the virus is spread, the large number of unrecognized infections indicates that attainment of epidemics cannot be expected from the isolation of the patient and immediate contacts, even though these may represent an appreciable number of infected individuals.

A study of two English villages (Goffe and Parfitt, 1955) attests the futility of such measures to eliminate the spread of virus. In this instance, despite the fact that family contacts were quarantined for two months following recognition of cases, virus was isolated six weeks later from the feces of a school child and demonstrated for two months in sewage drawn from areas of the larger village (population 7,400) in which no "cases" were ever recognized.

During an epidemic period all fevers in children should be regarded with suspicion. Bed rest is advisable pending diagnosis but is apparently not of great importance unless signs of central nervous system invasion are apparent. Unnecessary visiting should be discouraged and schools should be closed if they represent concentrations of children drawn from a wide area. Elective nose and throat operations and possibly all parenteral inoculations should be postponed.

Patients may be cared for at home, if home facilities and medically supervised care are adequate, or may be discharged to such a home when there is no medical indication for further observation or treatment in the hospital. Patients with poliomyelitis, or assumed to have acute poliomyelitis, are admissible to a general hospital provided that appropriate isolation precautions are employed. No special isolation or "pest" facilities are necessary.

It should be recognized, however, that with a few exceptions the above regulations are illogical in that they are designed to postpone the inevitable, i.e., final infection with the virus, to a later age. There is considerable evidence that case fatality rates and percentage of total disability increase progressively with age (Howe, 1952b, pp. 303-304). Obviously, immunization provides the answer to this dilemma.

Passive immunization with gamma globulin is too transient and costly to be of general value (Hammon and others, 1953), although it may have applications to special situations where the risk of exposure can be adequately assessed. In recent years, the development of formol-inactivated trivalent poliomyelitis vaccines has proceeded at a vertiginous rate. The first trivalent vaccines made from monkey CNS tissue (Howe, 1952a) were rapidly supplanted by preparations from tissue cultures of monkey kidney which had the advantage of higher antigenic titer and relative freedom from extraneous potential allergens (Salk, 1955). These vaccines have become available commercially and their effectiveness has been demonstrated in a field trial of unprecedented extent and thoroughness (Evaluation of 1954 Field Trial of Poliomyelitis Vaccine). For example, a "blind" study was carried out in which 402,000 children were vaccinated, of whom half served as controls since they had received only a placebo of tissue culture fluid containing no poliomyelitis antigen. In these two groups the rates for laboratory-verified cases of paralytic poliomyelitis were five times higher in the controls than in the immunized (35 and 7 per 100,000, respectively). Differences of only slightly less magnitude were noted in 221,000 second grade children, for whom 321,000 first and third graders served as uninjected ("observed") controls. These differences were of sufficient magnitude to rule out sampling variation and give an unequivocal answer as to the immediate effectiveness of this type of vaccine. For a discussion of certain long-term problems in immunization see "The Biology of Poliomyelitis, 1955."

Adequate provision should be made in the health program of a community for after care of patients who have passed through the acute stage of poliomyelitis. Expert orthopedic consultation and facilities are needed to afford maximum opportunities for recovery and speedy restoration of function with such prosthetic devices and operative procedures as are required. Not only must a patient be rehabilitated physically, but equally important is the emotional, social and occupational rehabilitation.

## COXSACKIE VIRUS INFECTIONS

By the experimental inoculation of suckling mice, Dalldorf and Sickles (1948) recovered a viral agent from the feces of two children with symptoms of poliomyelitis living in the town of Coxsackie, New York. The agent differed from poliomyelitis virus in that it was pathogenic for suckling mice and hamsters but not for rhesus monkeys. It induced striking lesions in the skeletal muscles of the experimental animals but not in the central nervous system (Dalldorf and others, 1949). Following this lead the work of many investigators soon demonstrated that viral

agents similarly capable of producing characteristic lethal illnesses in suckling mice and hamsters could be recovered from fecal specimens not only of cases of poliomyelitis but also from patients with other diseases and from healthy individuals. By comparison of their immunologic and pathogenic properties, it was found that these viruses were not a homogeneous group. Efforts to appraise their significance in human pathology required type differentiation and epidemiologic evidence to establish their causal relationship to clinical syndromes. These studies have gone forward rapidly and it now appears highly probable that agents of this type are implicated in the causation of two syndromes, clinically differentiated many years ago, namely, herpangina and epidemic pleurodynia (Bornholm disease). Possibly there are others (Huebner and others, 1952).

**Virus Properties.** The Coxsackie viruses are extremely small in particle size, ranging from about 25 to 35 m $\mu$ . They are relatively stable. Suspensions may be preserved frozen at  $-70^{\circ}\text{C}$  or  $-20^{\circ}\text{C}$  for long periods without significant loss of titer. They survive long exposure to a wide range of pH values, and temperatures as high as  $60^{\circ}\text{C}$  or above for 30 minutes are required for inactivation. They exhibit complete resistance to ether and also to such antibiotics as have been tested (penicillin, streptomycin, chloromycetin).

**Type Differentiation.** Up to the present, 15 different types of Coxsackie viruses have been differentiated by immunologic procedures. Many strains have not been classified and it seems probable that additional types will be found. Until knowledge advances to a point where systematic nomenclature can be developed, the types have been arbitrarily named by investigators who isolated them. Thus, in the laboratory the following types have been found to be antigenically distinct (Carter and others, 1952): Connecticut 5; Ohio 1; Nancy; Texas 1, 12, 13, 14, 15; Easton 10, 14; Boston 1, 2 and 3; Alaska 5; Israel 7. Evidence permitting the differentiation of types is obtained by means of cross neutralization tests in mice, cross complement-fixation tests, protection tests in mice born of immune mothers and cross protection tests in chimpanzees. The results obtained by each of these methods have been consistent.

Further classification of these types into two groups, A and B, has been proposed by Dalldorf on the basis of pathologic differences produced in suckling mice (Gifford and Dalldorf, 1951). Group A viruses, which include 8 to 11 serologically distinct types, characteristically produce extensive liquefaction necrosis of skeletal muscles and virtually no other observable pathologic findings in suckling mice and hamsters. Group B viruses, which include at least four types, produce only mild to moderate focal muscle lesions while also causing a characteristic encephalomyelitis and extensive pancreatitis as well as other visceral lesions in both suckling mice and adult mice.

**Diagnosis of Human Infection.** Coxsackie viruses have been isolated from human sources by inoculation of suckling mice with material properly treated from feces, throat swabs, pharyngeal washings and anal swabs. Evidence that the individual from whom the material originated was infected is obtained when a rise in serum antibody is demonstrated by neutralization test with the strain of Coxsackie virus which has been recovered. Complement-fixation tests performed with human serum show in many instances responses to types other than the one isolated from the patient. These heterotypic responses are often equal to or greater than the response to the homotypic virus. Accordingly, the complement-fixation test is of little value in the diagnosis of human infection. For the present, the identification of Coxsackie virus infection can be made only by a few research laboratories equipped with the required facilities and viral reagents.

**Host-Virus Relationship.** The general pattern has been outlined by the observations of Melnick and Kaplan (1953) on chimpanzees. After the virus is admin-

ed by the oral route to an animal, a viremia may be detected in a few days. In addition, virus can be recovered from the throat commencing in two or three days following the ingestion of the virus. The agent persists in the throat for about a week. Within two to four days virus is also excreted in the stool and can be found in the stools for two or three weeks or even longer. Neutralizing antibodies to the virus when orally make their appearance within two weeks and maintain the same titer for at least one to two years.

The response of the chimpanzee is such that if several weeks or months after the initial oral administration of the virus the same strain is again administered virus can be detected in the feces but only for a period of three or four days, during which time it is presumed that the virus is passively transported through the alimentary canal. Under such conditions, a true carrier state does not develop and isolation of the virus from the blood or throat is not possible. If now, however, the chimpanzee is given virus of a different type instead of the same type, the animal responds as though it has encountered virus for the first time with the development of the true carrier state and of new antibody to the heterotypic virus. A chimpanzee which has thus been exposed to two different types of Cocksackie viruses is now immune to these two types; yet, if a third and antigenically distinct virus is fed to the animal, it will again react to the agent like a new animal. Infections in the chimpanzee are otherwise asymptomatic.

Melnick and Kaplan further observed that Cocksackie viruses had no effect on the infection of chimpanzees with three different antigenic types of poliomyelitis virus. Both poliomyelitis and Cocksackie viruses set up independent infection without apparent interaction between them.

There is evidence to indicate that the reaction of the human host to Cocksackie viruses may be much the same as that of the chimpanzee insofar as inapparent infections are concerned. Serological surveys of population groups have revealed that antigenic contact with multiple types of Cocksackie virus is a common experience (Seeman and others, 1952). Recovery of a Cocksackie virus from the throat or stools, together with demonstration of a rise in neutralizing antibody in the blood stream, is not sufficient to prove a causal relationship with the illness from which the patient is suffering. Cocksackie virus may be coincidental with, and independent of, an infection with another pathogenic agent which is the real cause of the symptomatology. Failure to recognize this fact led to a great deal of confusion about the appraisal of the pathogenic potentialities of the strains of Cocksackie viruses. They have been recovered from persons suffering from a variety of clinical syndromes including paralytic and nonparalytic poliomyelitis, poliomyelitis-like syndromes, "summer gripe," aseptic meningitis, influenza-like illnesses, fevers of unknown origin, herpangina, epidemic pleurodynia (Bornholm disease). Only with the last two is the evidence of an etiological relationship convincing.

**Occurrence.** From the reports available, it is apparent that Cocksackie viruses are widely distributed. They have been identified in parts of North America, Europe, Africa, Asia and Australia. Isolations have been made from human pharyngeal secretions and feces, from domestic sewage and from flies. Whether an extrahuman reservoir exists is not known. For the present the assumption is justified that these viruses are part of the microparasitic flora of the alimentary tract of man which is propagated by passage from person to person. Frequency of exposure is determined by conditions of living, personal hygiene, and sanitation. Infections are largely inapparent. As causes of morbidity these viruses are unimportant. Their dissemination in human society can be reduced but not obviated. Freedom from any morbid annoyance which they may occasion is gained by the acquisition of immunity as a result of natural infection.

## HERPANGINA

Herpangina was first described as a distinct clinical entity by Zahorsky in 1919. This mild febrile disease of childhood, characterized by small to minute ulcer lesions of the posterior part of the mouth and throat, received little attention, however, prior to the publication of the studies in the Parkwood, Maryland, and Westmont, Virginia, communities, and in Washington, D. C., hospitals by Huebner and others (1952).

**Clinical Course.** The incubation period is brief, two to four days. Following a brief clinical description of the disease as given by Zahorsky: "The disease begins suddenly as an acute febrile movement. The temperature often rises to 104° F. Convulsions may occur. Vomiting is often present; anorexia and prostration are sometimes marked. Throat and posterior part of the mouth show minute vesicles; some of these have ruptured small punched out ulcers. They occur on the anterior pillar of the fossae, the tonsils, the pharynx and on the edge of the soft palate. The number of lesions varies from two to twenty. Dysphagia is often marked. The general and local symptoms disappear in a few days. The disease may be easily confused with ulcerative stomatitis, which sometimes begins in the throat. Prognosis is favorable and treatment is symptomatic."

Among closely associated individuals with the same infection, characteristic vesicles or ulcers may be present in some and not in others. The febrile illness lasts from one to four days, with a mean of about 2.5 days. The blood leukocyte counts are usually normal or slightly elevated (Parrott and others, 1951).

**Etiology.** In their etiological investigations, Huebner and his associates demonstrated the presence of one or more of the six Group A immunological type-Coxsackie virus in feces or throat secretions, or both, of 85 out of 99 cases clinically diagnosed as having had herpangina. Fecal specimens examined concurrently for the presence of virus were found positive in 60 per cent of neighborhood contacts, 40 per cent of familial associates and 3.5 per cent of other normal persons living in the same communities, and hospitalized patients with other diagnoses. Serologic tests performed on specimens from familial associates of invaded households demonstrated that infection occurred only in persons without preexisting type-specific neutralizing antibody, whereas persons with previous antibody with similar exposure within the household did not become infected with homotypic virus (Beer and others, 1952). It was further concluded from these observations that children become infected repeatedly when subsequently they are exposed to different strains of virus, so that as they become older they are immunized against many virus types. The frequency with which these infections cause clinically apparent illness is undetermined. Specific neutralizing antibody thus acquired persists for at least one year and probably for many years. Thus, available evidence justifies the concept that brief acute febrile episodes of this nature, including the syndrome of herpangina, may represent a common form of the disease induced in man by the number of different types in Group A of Coxsackie viruses.

**Occurrence.** Reports on the occurrence and distribution of cases of herpangina are still quite fragmentary. It appears to be a common disease of childhood with a seasonal distribution like that of poliomyelitis. Epidemic spread occurs principally in the summertime. Cases become rare in the winter months. There seems to be no doubt that the infection is propagated from person to person by some form of intimate contact, but whether virus contained in nasopharyngeal secretions or in saliva or material or both, are media of dissemination is a matter of uncertainty.

## EPIDEMIC MYALGIA OR PLEURODYNIA (BORNHOLM DISEASE)

This clinical syndrome was first described in Norway by Daare who published a paper in 1872 entitled "Epidemic of Acute Rheumatism in Drangedal Spread

contagion." Two years later, Jon Finsen stated "rheumatism of the muscles of the chest, pleurodynia, assumes here in Iceland an epidemic character. Such an epidemic is called 'taksött,' i.e., epidemic stitch in the chest. Twice I have observed such epidemics, namely, in the summer of 1856 and in the same season of 1865." In the United States, a small epidemic of a similar condition was independently described by Dabney in 1888 around Charlottesville, Virginia, where it was popularly designated "Devil's grip." Thirty-five years later, Payne and Armstrong described an outbreak in Virginia as "epidemic transient diaphragmatic spasm." Independently, in the same year, Hanger and his associates reported the occurrence of an epidemic mild fever of unknown nature and from a clinical study of 16 patients admitted to the Presbyterian Hospital in New York proposed the designation "epidemic pleurodynia." General recognition of the disease in this country and abroad dates from the classic monograph by Enjar Sylvest (1934) entitled "Epidemic Myalgia (Bornholm Disease)," which contains a complete review of the literature up to the time and presents a detailed description of its clinical and epidemiologic aspects.

**Clinical Course.** The incubation period is two to four days. The characteristic feature of the disease is sudden onset of pain in the thoracic or abdominal region. The pain may be referred to either or both sides, to the epigastrium, the lower part of the chest or lower part of the back, less frequently to the shoulder region and extremities. It is aggravated by the use of the muscles involved. When the intercostals or diaphragm are affected, the patient tries to reduce respiratory excursions as much as possible. Breathing may become shallow and very rapid. There may be a single paroxysm lasting a few hours or it may recur one or more times, progressively increasing in severity. Tenderness on pressure and pain on motion may persist for some time.

Pain is usually accompanied by fever of variable heights and duration. There may be anorexia, nausea or vomiting at the onset. Headache is a common symptom; stiffness of the neck or back is occasionally noted. Features of pleurodynia and aseptic meningitis may be present in the same individual, with an increase in the number of leukocytes in the spinal fluid. The total and differential white blood cell count are within normal limits. The illness lasts from two or three days to two or three weeks, the average being about one week. Invariably all patients recover but convalescence may be protracted. Differential diagnosis, particularly of sporadic cases, is difficult. Appendicitis, abortive poliomyelitis, common duct obstruction, pancreatitis, coronary occlusion, pneumonia and pleurisy are some of the conditions which may be simulated.

**Etiology.** Several investigators have recently reported the recovery of Group B strains of Cocksackie virus from stool specimens of patients with typical symptoms of epidemic pleurodynia. In some cases a coincident increase in neutralizing antibody for the strain recovered was demonstrated. Laboratory infections with strains belonging to Group B produced pleurodynia-like illness (Shaw and others, 1950). One such strain was instilled into the nose of a volunteer (Findlay and Howard, 1950). Forty-six hours later he developed a typical attack of epidemic pleurodynia. Complement-fixation reaction which was negative at 24 hours after onset was positive at 72 hours and persisted for a period of 9 weeks. Accordingly, present evidence supports the concept that epidemic pleurodynia is caused by one or more of the Group B Cocksackie viruses. However, for the present, confirmation of the clinical diagnosis by laboratory tests is a research procedure.

**Occurrence.** Although in reports so far available the epidemic occurrence of this disease has been stressed, it undoubtedly exhibited endemic prevalence as well. Geographic limitations are not yet apparent but enough evidence is available to indicate that it is widely distributed in North America and in western Europe. It has a seasonal distribution much like that of poliomyelitis, peak incidence being

reached in the latter part of the summer with a decline and extremely low incidence during the winter months. The age distribution varies with the locality but a representative experience is given in a monograph by Sylvest (1934) based upon 8 cases reported in Denmark in the years 1931, 1932. About 1 per cent was in infants under one year, 10 per cent in preschool children, 26 per cent in children 7 to 14 and 63 per cent in adults. The infection is apparently propagated by some form of person-to-person contact. Whether this is effected by the virus contained in saliva material or in throat secretions, or both, is uncertain.

### INFECTIOUS HEPATITIS

#### *(Infectious Jaundice, Epidemic Jaundice)*

Beginning with the latter part of the eighteenth century, reports appeared from time to time of epidemics of a mild febrile illness characterized by jaundice, occurring in scattered localities, in towns, institutions, villages, cities, and sometimes spread more widely. This epidemic jaundice was particularly prevalent among troops during military campaigns. It is stated, for example, that there were 42 cases of jaundice in Federal troops during the Civil War, with a case fatality of 0.4 per cent. During World War I, it prevailed from Belgium to Gallipoli, affecting troops on both sides. Similarly, in World War II, it was an important cause of morbidity. The official statistics give no adequate idea of the prevalence of disease, as large numbers of men continued on duty throughout their illness. According to Gauld (1946), because of its protracted convalescence infectious hepatitis was the greatest cause of disabling illness among the United States forces in the Mediterranean (North African) Theater of Operations. During the 27-month period, January 1, 1943, to March 31, 1945, there were over 35,000 cases of disease reported among American units in the theater. In the autumn of 1943,

tain squadron of the air corps stationed in Sicily, between 35 and 40 per cent of the command were attacked over a three-month period, and this seriously interfered with the operations at that time. At the peak of the epidemic, in the winter of 1944-45, weekly attack rates as high as 13 per 1,000 were recorded by certain divisions of the Fifth Army, and this, if maintained, would be equivalent to an attack rate of 5 per cent per month. The case fatality rate was 0.18 per cent for the three-month period. Other allied troops and axis troops in the theater suffered similarly.

In 1886, Weil clinically differentiated from infectious jaundice the disease which bears his name (Weil's disease). Later, this disease was shown to be due to *leptospira* conveyed to man through contact with rats, dogs and other animals (see leptospirosis). Blumer (1923) reviewed the occurrence of infectious jaundice in the United States, distinguishing it from the leptospiral disease. He obtained records of 11 outbreaks occurring from 1812 to 1886 and 51 outbreaks occurring between 1886 and 1920. They were scattered in almost every state of the Union. During the winter of 1921-22, the disease was widely distributed over New York State. Huntington Williams (1923) analyzed some 700 cases reported from more than 100 different communities. From these and other studies it appeared that the disease might occur at any time during the year but was more prevalent during the fall and winter months. In some populations it was largely a disease of childhood and adolescence. For example, in the New York State outbreak, 7 per cent of the cases were among preschool children, 52 per cent among school children 5 to 14 years of age, and 18 per cent in young adults 15 to 24 years, the rest being in older persons.

**Clinical Course.** As a rule the onset is rather abrupt with fever, anorexia, nausea with or without vomiting, lassitude, headache, pain in the back and limbs, and abdominal discomfort, especially in the right upper quadrant. There is no striking change in the blood picture except an early tendency toward leukopenia. After four or five days, the fever subsides, bile may be detected in the urine, clay-colored stools may be passed and clinically recognizable jaundice may appear. It varies in intensity from an icteroid tint, scarcely visible except in the sclerae, to a deep yellow, almost bronze tint. Its appearance may be delayed to as late as the twentieth day. It generally persists from a week to 10 days but may disappear after a few hours or may persist for six weeks or longer. Convalescence may be prolonged and relapse is not uncommon. About 5 per cent of cases continue to have evidence of hepatitis four months after onset, rarely longer. There is great variation in the severity of the disease, depending upon the amount of damage done to the liver cells by the virus. The very mild infection without jaundice can be recognized only if searched for with the aid of a liver function test. The proportion of infections without fever and jaundice, i.e., subclinical, is unknown, but not inconsiderable. The very low fatality in most outbreaks is a striking feature.

Blumer was one of the first to point out that the afebrile cases of infectious jaundice are clinically indistinguishable from "catarrhal" jaundice, and felt that there was justification for assuming that catarrhal jaundice was merely a name for a sporadic case of infectious jaundice. Patients dying from infectious hepatitis may present the clinical picture of acute yellow atrophy. Acute yellow atrophy is not a distinct disease entity but a syndrome which may result from the destructive action of a variety of agents on the liver cells.

**Infectious Agent.** A series of experiments carried out on human volunteers during World War II, established the virus etiology (MacCallum and Bradley, 1944; Havens and others, 1945). The disease was transmitted to human volunteers by feeding them duodenal contents from a patient with the malady and by parenteral injection of serum and whole blood and by feeding fecal material obtained from

patients. While the observations were necessarily limited, they indicated that virus was present in the blood stream of the patient before the onset and during the acute stage of the jaundice. Attempts to demonstrate the virus in urine and nasal pharyngeal washings of patients were unsuccessful. The virus was demonstrated to be in the blood and feces one month after onset of the disease and a three weeks after disappearance of jaundice (Neefe and others, 1945). Whether the patients who have relapse have the virus in blood and excrete it in the feces has not yet been determined, nor has the duration of the carrier state been ascertained.

In spite of diligent search by many investigators, no experimental animal has been found susceptible to infection with this virus. Knowledge of its characteristics is accordingly limited. It appears to be markedly heat stable, being resistant to a temperature of 56° C for at least 30 minutes. Henle and others (1950b) and Drake and others (1950) were successful in transferring the agent from cases of infectious hepatitis to chick embryo tissue culture and to embryonated hen's eggs. It was passed in series and proved capable of inducing hepatitis in volunteers. It was also found (Henle and others, 1950a) that amniotic fluids of the fifth to seventh amniotic passage series after inactivation by ultraviolet light yielded a serum test antigen which appeared specific in that positive results were obtained with convalescents of natural as well as experimental infectious hepatitis. The virus which causes "infectious canine hepatitis" in dogs is not known to be related in any way to the virus which causes infectious hepatitis of man.

**Incubation Period.** Epidemiological evidence from many sources indicated that the incubation period of infectious hepatitis was usually from three weeks to one month. However, in some outbreaks (Gauld, 1946) the evidence suggested that it was shorter, in the neighborhood of 10 to 16 days. From the results of experimental inoculations of human volunteers, it appears that clinical signs may become evident as early as 9 and as late as 38 days after inoculation. The average incubation period is 23 to 24 days. This is a distinguishing characteristic.

**Mode of Spread.** There is almost unanimous agreement that infectious hepatitis is spread by some mode of person-to-person contact. An epidemic moves at a leisurely pace through a population, usually taking several months to run its course. Cases are scattered in time, place and persons. In outbreaks in civil communities (Davis and Hanlon, 1946; Lilienfeld and others, 1953) there is a marked tendency toward familial aggregation; the risk of contracting hepatitis for members of a household of a primary case is as great or greater than a similar risk in scarlet fever, diphtheria or bacillary dysentery. Approximately two thirds of the patients report association with a recognized case, either at home or at school. That person-to-person contact was the principal mode of spread in military organizations was the conclusion drawn by Gauld (1946) from his epidemiological field studies of infectious hepatitis in the Mediterranean Theater of Operations during World War II.

Concerning the exact mode of transmission there is some uncertainty. Since the virus has been demonstrated in the feces of infected individuals, and there is some apparent association of the disease with unsanitary living conditions, it seems probable that fecal dissemination is an important mode of transfer. In spite of the failure in a limited number of human experiments to demonstrate the presence of the virus in the nasopharyngeal secretions of infected persons at the beginning of their illness, the possibility of respiratory transmission must still be recognized. The seasonal distribution is suggestive of a respiratory mode of spread rather than transmission through the gastrointestinal tract; possibly both mechanisms are operative. There is no evidence to support the concept that the infection is carried by an arthropod vector, although it is possible that at times flies may play a mechanical role in contaminating food.

Occasionally, explosive outbreaks occur due to dissemination by a common

edium. Possible illustrations are the water-borne outbreak in a summer camp investigated by Neefe and Stokes (1945); the milk-borne outbreak investigated by Murphy and others (1946); and the food-borne outbreak investigated by Read and others (1946). Warren (1953) has reviewed the outbreaks which have been reported in the past 15 years and classified them according to probable mode of spread.

Finally, the virus may be transferred artificially from an infected to a susceptible individual by transfusion of blood, plasma or serum, or by the use of improperly sterilized syringes or needles (Droller, 1945). Even the minute amount carried over in the syringe or needle, used without proper sterilization between patients, may be sufficient to infect. In either event the inoculated individual if susceptible will come down with the illness after an incubation period of from 9 to 38 days, thus differentiating the virus of acute infectious hepatitis from that of serum hepatitis which will be discussed later.

**Prevalence.** On account of the mildness of the disease, the frequency of subclinical or inapparent infections, and because routine reporting to health authorities is not required, infectious hepatitis is much more widely prevalent than is appreciated. The fact that it is principally a disease of children and adolescents argues for the interpretation that most individuals have acquired immunity by infection before they reach adult life. In the larger urban communities it is probably more or less constantly prevalent on an endemic level. When the virus has been absent from a community for long periods of time and a susceptible population has accumulated, if the disease is introduced by an infected individual it may spread widely causing an epidemic. This perhaps explains why epidemics are more frequent in isolated towns and institutions.

**Control.** There is little that can be done to prevent or postpone exposure to the virus of infectious hepatitis except by general measures of personal cleanliness, home hygiene and community sanitation. Recognized clinical cases should be isolated for a week following onset, with appropriate attention to safe fecal disposal. Interference with the activities of familial contacts is not justified. When a group of cases occurs in a short period of time in a community, school, institution, or military organization the possibility of dissemination by a common vehicle, water, food or milk should be investigated. In any case inquiry should be made into the possibility of infection by transfusion of whole blood, plasma, or serum, or by contaminated needles or syringes used in parenteral injections.

Durable protection can be gained only with immunity acquired through recovery from clinical or subclinical infection. Human gamma globulin confers temporary passive protection if given during the incubation period up to within six days before the onset of the disease. The dosage necessary is about 0.02 ml. per lb. body weight (intramuscularly). The protection afforded by this procedure may last six or eight weeks, or more. It is recommended for exposed persons who because of their general condition are poor risks for any infectious disease, and it may be used effectively to check an institutional epidemic (Havens and Paul, 1945; Capps and Stokes, 1952).

## SERUM JAUNDICE

(*Homologous Serum Jaundice, Serum Hepatitis, Hepatitis B*)

Between October, 1883, and April, 1884, a jaundice epidemic attacked personnel of the shipbuilding and machinery factory in Bremen, Germany. It was investigated by Dr. A. Lürman (1885). His report is an example of careful, painstaking observation, which led to a clear logical inference completely out of the sphere of the existing knowledge and theory of his time. The clinical course of illness was not essentially different from that which had been described in many of the previous epidemics of jaundice. In all patients it began with symptoms of gas, or gastrointestinal catarrh which lasted at least eight days, and sometimes for weeks before the appearance of jaundice. During this time, the patients complained of pressure and fullness in the region of the stomach, loss of appetite, nausea, vomiting, dizziness, disinclination to work, etc.; more frequently, constipation was present, seldom diarrhea. He mentioned as diagnostic signs clay-colored stools and presence of bile in the urine. None of the cases was fatal. The illness lasted months in one instance, but usually followed an afebrile course of only a few weeks' duration. By systematic analysis of the habits and activities of those who became ill in comparison with those who had not, he excluded the etiological factors which had been considered in previous epidemics, such as atmospheric influence, bad diet, liquor and drinking water. The only factor which he found to be common to those who had become ill was vaccination against smallpox which had been carried out on all employees between August 14 and September 1. Humanized glycerine lymph was used by the scarification technique, employing vaccination lancets; after each vaccination the instrument was washed in 1 per cent carbolic solution. Among 1,289 persons vaccinated, 191 developed jaundice at an incubation period ranging from two to eight months. Of 87 persons vaccinated by other physicians and with other lymph none became ill. Among about 500 persons

workers employed after termination of the vaccination period, none succumbed to icterus. Lürman was unable to give an explanation for the strange causal connection.

It was many years before the possibility of transmission of jaundice by parenteral inoculation of human serum was again considered. In England, during 1937, 41 of 109 recipients of a single batch of measles convalescent serum administered subcutaneously developed jaundice after an incubation period ranging from 16 to 114 days, and eight died of hepatic necrosis. This report was amplified by a memorandum prepared by the Medical Officers of the Ministry of Health (1943) entitled "Homologous Serum Jaundice." In addition, reference was made to a similar outbreak, investigated by Chesney and others in 1942, in 266 British troops who were each given less than 14 ml. of Seitz-filtered mumps convalescent plasma in one or two doses intravenously; 86 developed jaundice. It was furthermore stated that 12 cases of jaundice had been reported from several sources in persons who had previously been given transfusions of plasma or whole blood.

In the meantime, Findlay and MacCallum (1937) reviewing their experience during the previous four and one-half years in developing a satisfactory preparation of yellow fever vaccine, reported that among 2,200 persons immunized there had been 52 cases of jaundice, developing from two to seven months after the inoculation. They suspected that the source of the icterogenic agent was in the human serum used in the preparation of the vaccine but were unable to prove it conclusively. In a much larger experience in Brazil, Soper and Smith (1938) and Fox and others (1942) reported the occurrence of jaundice after a long incubation period in individuals who had received certain lots of yellow fever vaccine in which human serum was used in very small amounts to stabilize the virus. Yellow fever vaccination was made compulsory in the U. S. Army and Navy during World War II. Beginning in March, 1942, there was a sudden great increase in the number of cases of jaundice reported from various posts of the Army, in and outside the continental United States. Investigations then instituted by the Army Epidemiological Board established a causative relationship with the administration of yellow fever vaccine. Seven out of some 130 lots which had been used were implicated. Evidently the icterogenic agent had been introduced with serum in human donor pools which had been added to these lots, and the antibodies from other donors to the pool were not sufficient to neutralize it. Although the amount of human serum in each ml. of vaccine was exceedingly small, it was sufficient to infect and cause clinically recognizable disease in 10 to 15 per cent of the recipients (Sawyer and others, 1944). Administration of yellow fever vaccine containing serum was discontinued on April 15, 1942, but because of long incubation period, cases of hepatitis continued to occur throughout the year. A total of more than 51,337 cases and 62 deaths were reported in the Army (Walker, 1945). A serum-free preparation was substituted and no jaundice proved to be associated with yellow fever vaccination developed subsequently.

The discovery of the occasional presence of an icterogenic agent in human serum also offered an explanation for the observations which had been recorded for many years of the occurrence of jaundice among syphilitic patients treated with arsenical drugs or bismuth. It now became apparent that this form of hepatitis might result from transfer of the infectious agent by improperly sterilized syringes or needles. This mode of transmission was soon found to be not infrequent in clinic and hospital practice. Very little blood or serum of an infected carrier is necessary to transmit the disease. The causative virus resists the cursory type of sterilization often practiced in busy clinics in which numerous blood samples are drawn and many injections have to be given in a short time. During an ordinary venipuncture some of the blood may be sucked back from the syringe when the tourniquet is released, permitting infected material previously present in the syringe or needle to

enter the blood stream of the patient. During the course of an injection some blood or serum from the patient may be forced up through the needle during the contraction of the recipient's muscle thus resulting in contamination of the syringe, traces of blood serum left on the tip or within the needle when it is removed from the syringe may be aspirated in the barrel. Numerous reports of syringe-transmitted hepatitis have been made (Sherwood, 1950).

By way of summary of these and other studies, cases of homologous serum jaundice were traced (1) to transfusion of whole blood or plasma or serum, both fresh and preserved by freezing or drying from frozen state; (2) to the injection of convalescent measles and mumps sera; (3) to the injection of small amounts of human serum in yellow fever vaccine; and (4) to the accidental transfer of a drop or two of blood from one patient to another by an unsterilized syringe used for routine venipuncture or from "sterile" syringes often used for multiple injections of arsenicals and bismuth in syphilis clinics.

**Frequency of Transfusion Jaundice.** It follows that the frequency of jaundice is lowest in transfusions of whole blood from a single donor to a single recipient and greatest in transfusions of pooled plasma or serum. An illustrative experience in England is reported by Spurling and others (1946). They gave the results of follow up of 2,040 patients transfused with pooled serum, and or plasma, of 1,284 patients transfused with whole blood only, and 1,284 control patients not transfused who were in the hospital at the same time as those receiving whole blood. The incidence of jaundice in the patients receiving pooled plasma or serum was 7.3 per cent. No patient receiving whole blood developed frank homologous serum jaundice. There was no case of jaundice among the controls. Similarly, in New York State, Brightman and Korns (1947) followed up 649 patients who had received transfusions of dried pooled plasma and found the subsequent incidence of homologous serum jaundice to be 4.5 per cent.

**Source and Character of the Icterogenic Agent.** The icterogenic agent is present in the blood serum of an unknown but variable proportion of individuals who are apparently healthy and who present themselves as donors. There is no practical laboratory test available by which these individuals can be identified nor can they be excluded by the absence of history of previous suspicious illness. How the agent is propagated in human populations is unknown. All attempts to transmit it to experimental animals have failed. Knowledge of the characteristics of the virus has been gained from clinical observation and experiments on human volunteers. The agent is filtrable through Seitz EK filters which hold back bacteria. It is relatively heat stable, resisting 56° C for 60 minutes and is relatively resistant to the ordinary antibacterial preservative. It survives in a serum preserved by addition of merthiol 1:2,000 or of tricresol 0.2 per cent.

**Relationship of Epidemic Hepatitis to Serum Hepatitis.** Clinically serum hepatitis cannot be differentiated from infectious hepatitis. Moreover, infectious hepatitis has resulted from the injection of serum from an active case of infectious hepatitis. Whether the two icterogenic viruses are independent entities or variants of the same virus is yet to be determined (Stokes, 1953); they differ in the following respects:

(1) *Incubation period.* While the incubation period of infectious hepatitis is 9 to 38 days, average about 24 days, the incubation of serum hepatitis is much longer, 6 weeks to 6 months, average about 12 weeks.

(2) *Infectious hepatitis spreads by contact* among groups naturally exposed or by milk, food or water, while serum hepatitis rarely if ever spreads in this manner.

(3) In a limited number of human experiments, whereas infectious hepatitis has been reproduced by *feeding stools from active cases*, and sometimes by *feeding blood taken at the onset*, serum hepatitis has not been transmitted by feeding stools.

and only once by feeding icterogenic serum, although the latter may be readily transmitted by the parenteral injection of the serum.

(4) Observations on human volunteers confirm the epidemiologic experience that, while there is homologous immunity, patients who have had infectious hepatitis are susceptible to serum hepatitis and vice versa.

(5) While the administration of *gamma globulin* is apparently effective in prophylaxis of infectious hepatitis, its similar use for the prevention of serum hepatitis is disappointing. This may be due to the long period of viremia present in the long incubation period in patients with serum hepatitis.

**Prevention.** The prevention of serum hepatitis follows largely from what is known about its mode of transmission. Efforts to exclude the risk of transfer of the icterogenic agent in transfusion by examination of blood donors is not reliable. Individuals may have the virus in their circulating blood without having recognizable signs or symptoms. Nevertheless, every effort should be made to reduce the risk by careful examination of donors. Anyone should be excluded who gives a history of having had jaundice in the previous year, recent transfusions of blood or blood plasma, exposure to infectious hepatitis in the preceding few months, or who on examination is found to have fever, scleral icterus, biliuria, enlarged, tender liver.

Transfusion of whole blood from person to person is preferred to the practical use of pooled plasma. There does not exist at present a satisfactory method for inactivation of hepatitis virus in whole blood, plasma or serum. In a human experiment conducted by Drake and others (1953) gamma globulin prepared from the blood of homologous serum hepatitis convalescents did not protect volunteers against disease after injection with an unknown amount of virus as contained in blood or serum obtained during the early stage of illness from other volunteers.

In institutional, clinic and private practice, collateral causes of transmission of viral hepatitis can be removed by requiring that all instruments used to puncture the skin or to collect blood be sterilized by dry heat (160° C) for a minimum of one hour or autoclaving or boiling for about 15 minutes. More specifically, the recommendations are as follows: (1) that in the performance of venipunctures to collect blood a freshly sterilized needle or syringe be used on each patient; (2) that in skin punctures to draw blood for examination, a fresh heat-sterilized lancet be used for each patient (hollow needles should not be used for this purpose); (3) that in giving parenteral therapy and prophylactic immunizations of all types the same precautions should be taken. Injections should not be given to successive patients out of the same syringe. There is little evidence regarding the hazard of intracutaneous administration of skin-testing antigens, such as tuberculin, out of the same syringe. There is considerable advantage in ease of administration and economy of material when a 1-ml. syringe is filled and 10 successive intracutaneous injections given from it, the needle being flamed or changed between injections. The danger in this is probably too remote to outweigh its advantages. However, a tuberculin syringe should be discarded and resterilized when emptied.

## YAWS

(*Framboesia*, *Treponematosis*)

Yaws is a specific contagious disease prevalent among primitive peoples in tropics, resembling syphilis in its course and characterized by striking cutaneous manifestations. In the earliest stage there is a primary lesion in the form of an ulcer or granuloma, usually located on exposed portions of the body, particularly on legs, and often appearing at the site of a pre-existing wound. In from six weeks to three months after the appearance of the initial lesion, the patient suffers from malaise, headache, joint pains, with or without fever, and a secondary eruption develops. Papules and granulomatous nodules appear over various parts of the body. This generalized stage lasts from three to four months to two to three years, characteristic nodules coming out in successive crops in long-standing cases. In some patients, the process goes on to a tertiary stage with destructive bone, joint and skin lesions. Unlike syphilis, it does not attack the central nervous system or viscera and is not transmitted congenitally.

**Cause.** Confirming observations made by Thompson in 1820 and Maxwell in 1839, Pautet in 1848 inoculated 14 Negroes with a secretion from framboesia granulomata. All of them developed yaws in from 12 to 20 days. Native mothers in some areas were known to inoculate their children by scratching the arm and transferring the matter from the lesion of an infected person. They believe that children were bound to have the disease at some time and that the younger the child had it the easier it would be on them.

The causative agent *Treponema pertenue* was discovered by Castellani in 1905. It has been found in the epidermis of the yaws granulomata and demonstrated in lymphatic glands and spleen and in some instances in the bone marrow. The organisms are morphologically and culturally indistinguishable from *Treponema pallidum*. Furthermore, patients with yaws develop a positive Wassermann and flocculation test. Monkeys and rabbits can be infected by inoculation with discharges from yaws lesions. Experimental infections in rabbits with *T. pertenue* showed consistent and significant differences from those produced by *T. pallidum* (Turner and Chesnut, 1934). Nevertheless, there is a close immunological relationship between the two species of treponemas.

It has been demonstrated by experimental inoculation of man as well as animals that one attack of yaws confers a high degree of protection against reinfection. In man this immunity develops slowly. Within the first three years reinoculation may give rise to a modified attack of yaws but after a period of 10 years a majority of persons infected with yaws are refractory to reinoculation. According to Turner (1936) syphilis also confers some degree of immunity to yaws.

**Mode of Transmission.** Yaws is not a venereal disease. Infection in man occurs most commonly by contamination of a skin wound with secretions from an open lesion of an individual afflicted with the disease. This transfer may be media-

rough flies. Kumm and Turner (1936) advanced evidence which suggested that in Jamaica a minute fly, *Hippelates pallipes*, may play a role. Enormous numbers of these flies were observed on ulcerative lesions. Experimentally it was found that *pertenue* remained actively motile for about seven hours in the esophageal diverticulum of the fly. In the stomach and proboscis they lost their motility quickly. Rabbits could be infected by scarifying the skin and exposing them to *Hippelates pallipes* which had fed on infected discharges. These investigators suggested that mechanical transfer might occur by regurgitation of diverticulum contents from a preceding feeding. The relative importance of flies in transmission as compared with transfer by contact, fingers and objects contaminated by wound secretions, is undetermined and naturally varies with circumstances.

**Prevalence.** The requirements for transmission limit the distribution of this disease geographically and socially. It is primarily a disease of primitive peoples. It is encountered in equatorial Africa, and recently has been particularly prevalent in Kenya, Tanganyika and Uganda. There is evidence that the original home of yaws was among natives in Africa and that it spread to different parts of the world by the slave trade. However this may be, the disease was extremely common in West Indian slaves brought to the West Indies and tropical America, where it is still prevalent in certain populations. It has a scattered distribution among the peoples living in Southeast Asia and on the island archipelago adjacent to it—in the Malay Peninsula, Assam, upper Burma, Indochina, Dutch East Indies, Ceylon, the Philippines, Fiji and Samoa.

Where it is extensively prevalent, it is very largely a disease of childhood. About two thirds of the cases occur before puberty, although no age is entirely exempt. In a study of 23,000 persons living in a yaws-infested rural area in Jamaica, B.W.I., Saunders and Muench (1937) found that the proportion of the population with yaws increased rapidly to a level of 70 to 80 per cent at 15 to 20 years of age, after which there was a gradual decrease. Annual infection rates among previously unaffected persons rose sharply to a peak of about 20 to 30 per cent at eight years of age; this was followed by a more gradual fall. They found few new infections after 30. In other words, the disease prevailed so extensively in these areas that a majority of the population acquired immunity through attack before they reached maturity.

Turner and Saunders (1935) and Saunders and others (1936) called attention to the fact that yaws has remained localized in certain sharply limited areas in Jamaica, while having every opportunity to permeate all parts of the island. This suggests that in some localities there are factors limiting its spread and in others influencing factors to favor its propagation. Just what these factors are is not yet clear, although, in general, the prevalence of the disease is associated with areas in which there is a heavy rainfall, a fertile, moisture-holding soil supporting an abundant vegetation and a primitive population living under poor, neglected and insanitary conditions.

**Control.** Complete and permanent elimination of yaws from a primitive population can be effected through a profound change in the social and economic status, habits of life, and mental attitude. Nevertheless, a considerable degree of amelioration is possible under favorable circumstances by the reduction through treatment of sources of infection in a community. The disease is even more amenable to treatment than is syphilis, and through use of the same drugs. The administrative problem resolves itself very largely into the organization of appropriate stationary or traveling clinics. With the development of the use of penicillin, a definite advance has been made. With this drug, mass treatment carried on by a few clinics will bring a large measure of relief to an infected population. It must be followed up, however, by subsequent supervision of a district and by resurveys for the purpose

of discovering relapses and new infections, which in turn must be subjected to treatment. In the course of time, with repetition of this effort, the attack rate of yaws among susceptible persons can be greatly reduced, if not eradicated.

### LEPROSY

JAMES A. DOULL, M.D., DR.P.H.

Leprosy is a chronic specific infection, characterized by nodules in the skin and mucous membranes (lepomatous type) or by a macular eruption (tuberculoid type). Nerve changes, with resultant anesthesia, atrophy, and deformity, occur in both types. Secondary manifestations in the lepomatous type (mixed leprosy) but are primary and more severe in the tuberculoid. Acute exacerbations and remissions occur in both. There is a disturbance of calcium metabolism, the diffusible form usually being decreased and the colloidal increased. In lepomatous leprosy, complications, especially tuberculosis and amyloidosis, shorten life; in tuberculoid leprosy, life expectancy is unaffected.

The fear of leprosy is almost without parallel, due to biblical influence. Among many people, however, especially where the disease is prevalent, it is of no greater concern than tuberculosis is with us.

**Incubation.** It is difficult to place the period of incubation with any certainty. It is usually stated as from six to eight years, but may vary from a few months to 20 years. Leprosy develops very slowly and commonly exists several years before it is recognized.

**Prevalence, Geographic Distribution, History.** The number of cases in the world is estimated at more than three million. The story of the spread of leprosy over the globe is one long record of transmission by human travel. High endemic prevalence now is chiefly in the tropics, although every country has some cases, either imported or of domestic origin. The countries now having a high leprosy rate (above 5 per 1,000) have a hot climate with high annual rainfall. Asia and Africa number cases by the hundreds of thousands. There is some evidence that the epidemic course of leprosy runs for decades and centuries rather than weeks, months and years. The epidemiology of the disease tends to chronicity in the community as in the individual.

**IN EUROPE.** Five to six hundred years ago leprosy was prevalent throughout Europe. It is estimated that there were 19,000 lazarets, 2,000 being in France. The decline of the disease during the fourteenth and fifteenth centuries and

rise and fall in Norway during the nineteenth century are remarkable features in the history of the disease. At present it remains chiefly around the southern borders of the continent being still of public health importance only in Portugal, Spain, Italy, Rumania, Yugoslavia, Greece, and the U.S.S.R. Residual foci persist in several other countries.

**IN AMERICA.** Just when and how leprosy came to the western world is unknown. It is likely that it was brought in by slaves. It first attracted attention in the United States in the early part of the past century, when it was recognized in Louisiana. In 1902, a census showed 278 cases, the majority of these probably having contracted the disease in the United States. In 1955, the National Leprosarium at Carville, Louisiana, had about 310 patients; and counting discharged, absconded, those under private physicians and unrecognized cases, there were probably at least twice as many outside the institution. Except in the Gulf Coast states, especially Florida, Louisiana and Texas, leprosy shows little tendency to spread in the United States. A few persons have contracted the disease in California and Minnesota. Puerto Rico, the Virgin Islands (especially St. Croix) and the Panama Canal Zone have a fair number of cases.

Mexico has a high prevalence. The Central American republics have much lower rates. There are many cases of the disease in South America; the highest prevalence rates are found, in descending order, in Brazil, Venezuela, Paraguay, Colombia, Bolivia and Argentina. Brazil registers about 5,000 new cases annually.

**IN THE HAWAIIAN ISLANDS.** In the past century most of the islands of Oceania became infected. Among these, Hawaii is of special interest. The disease appeared probably about 1820 and by 1865 had become so much of a public health problem that the then Hawaiian government established a settlement on the island of Molokai, which has become famous from the fact that the Belgian priest, Father Damien, who labored among the patients, contracted leprosy. Prevalence reached its maximum about 1890 with 1,200 cases. Since 1949 new patients requiring isolation have been admitted to a new hospital, Hale Mohalu, Pearl City. On June 30, 1955, there were 325 patients at both institutions and 227 on conditional release. Only 20 cases were discovered in 1954-55. The disease from the beginning has been found predominantly among the native and part-native elements of the population, although other groups have been affected to some extent.

**Etiology.** Hansen (1874) described the bacillus of leprosy (*Mycobacterium leprae*). This was confirmed in 1879 by Neisser and subsequently by many other students of the disease. The bacilli are acid-fast and resemble morphologically the tubercle bacillus. They do not grow on artificial media and are not pathogenic for the lower animals. They are present in greatest numbers in nodules of the skin and mucous membranes, but are widely disseminated throughout the body and even occur in the blood during febrile stages which may precede the breaking out of fresh epromata (lepra reactions). The bacilli of leprosy are found crowded within actively phagocytic macrophages (lepra cells), which may become vacuolated (foamy cells), and within "globi," the nature of which is unknown. In the tubercloid form they are found in the nerves but often rarely or not at all in the cutaneous macules. They have been encountered in the spleen, liver and testicles; in fact, in all the lesions of the disease. Acid-fast bacilli resembling leprosy bacilli also appear in the feces and expectoration.

From the standpoint of prevention, the location and number of bacilli are important. They leave the body from any of the lesions which are broken down. They are discharged in enormous numbers from the degenerated nodules of the skin and mucous membranes. They occur in discharges from the mouth and nose, for lesions in the nose and throat are common. The bacilli that remain locked up in the nerves in the purely anesthetic cases present no public health hazard.

Hansen's bacillus is accepted as the cause of leprosy because it is invariably associated with the disease and often in great numbers, but Koch's laws are far from being complied with. We really know little about this bacillus. Acid-fast bacilli occasionally have been cultivated from leprotic lesions by different methods and by a number of bacteriologists, but these cultures show considerable variation and apparently represent a number of species. Except in these instances, no method of cultivation, including tissue culture and addition of various symbionts, has been successful, even when the inoculated tissues have been teeming with acid-fast bacilli. The unfortunate lack of a susceptible experimental animal is a serious handicap to the identification of the leprosy bacillus.

**Immunity.** Leprosy is a disease of man only. As far as is known, somewhat similar diseases in rodents, water buffalo, fish and birds have no relationship to human leprosy. There is no racial immunity. The long incubation period, chronic course and tendency to spontaneous healing indicate that the body must possess a high degree of resistance to this infection. Rogers believes that at least 50 per cent of persons infected do not develop clinical leprosy. The lepromin test introduced by Mitsuda in 1916, when positive, apparently is an indicator of resistance. Lepromatous patients nearly always give a negative result; tuberculoid are positive in the great majority of instances.

Highest attack rates are seen in those who have been exposed in early life. In the Philippines, the incidence is highest at 10 to 14 years of age. Above the age of 30 years the liability to contract the disease, even when exposed in the household, rapidly decreases, although no age period is entirely exempt. Fifty per cent of cases occur before 20 years of age and 66 per cent before 25 years; few cases start at 30 years. In this regard leprosy is somewhat like tuberculosis. These well-established facts bear upon prevention.

Lepromatous leprosy usually is about twice as frequent in males as in females. This may be due to relative susceptibility of the sexes, or to modes and opportunities of infection.

Many leprosy patients become tuberculous, especially in the late stage; in fact, leprosy is one of the number of infections that predispose to tuberculosis. Tuberculosis and leprosy have many points of resemblance. There is special susceptibility in childhood and early adolescence; in both diseases resistance develops with maturity. A point of difference is higher incidence of tuberculosis among females in early adult life.

From Deull, Guinto, Rodriguez and Bancroft, *Internat. J. Leprosy*, 10:107, 1942.

Fig. 5-1. Annual incidence of leprosy, Cordova and Talisay, P. I., by age groups.

There is an interesting serological relation to syphilis. In Cochrane's series (1947) the percentage of patients with a positive Wassermann varied from 41 per cent in lepromatous cases to only 4.5 per cent in neural; antiluetic treatment in a small series did not affect the reaction. Most leprologists consider that a positive Kahn or Wassermann in the great majority of instances is attributable to leprosy and not to syphilis.

**The Experimental Disease.** Leprous material has been inoculated into human beings by Danielssen, Profeta, Cagnina and Bargilli with negative results. However, most of these experimental attempts were done on adults who are resistant to this infection. In Arning's well-known case of the convict Keanu, who was pardoned on condition that he allow himself to be inoculated with leprosy, the disease did develop, but the experiment is somewhat spoiled by the fact that the man lived in a leprosy focus and had leprosy relatives. In this case a piece of leprosy material was planted into the subcutaneous tissue of the left arm. One month after the inoculation, pain appeared in the arm and shoulder and four and one-half months later a typical leprosy nodule was found. Four years later the patient had advanced leprosy.

Many unsuccessful attempts have been made to transmit leprosy to the lower animals. Lesions simulating leprosy have been reported in the guinea pig (Clegg); in the Japanese dancing mouse (Sugai); in rats (Marchoux); in the monkey (Nicolle, Duval, McKinley). It is questionable, however, whether the disease has been reproduced in the lower animals. Rat leprosy needs separate mention.

**Rat Leprosy.** There is a disease among rats which is a close counterpart of leprosy in man. It occurs naturally in *Rattus norvegicus* and may be transferred by inoculation to the more tractable laboratory white rat. The disease was first observed by Stefansky in 1903 in Odessa. In the same year Rabinowitsch found the disease among the rats of Berlin, and Dean in 1903 discovered it independently in London, and in a later publication (1905) reported success in transferring the infection by artificial inoculation. Since then rat leprosy has been found by Tidswell in the rats of Sydney, Australia; by Kitasato in Japan; Marchoux and Leboeuf in Paris; and the English Plague Commission observed the disease among the rats in India. Wherry and McCoy found a number of cases among the rats caught in San Francisco, and Krakower and Gonzalez a naturally infected mouse in Puerto Rico.

The proportion of rats infected with leprosy in different localities varies greatly; thus in Odessa and Paris from 4 to 5 per cent; in San Francisco 0.2 per cent; in Sydney only 0.001 per cent; and in Honolulu more than 16,000 rats were examined by officers of the U. S. Public Health Service before a positive finding by Badger in 1935. The fact that the infection is, relatively, so rare in Honolulu suggests that this rodent plays no part in the epidemiology of the human disease.

Leprous rats in a late stage of the disease are usually recognized by the presence of patchy alopecia associated with cutaneous and subcutaneous nodules which may be the site of open ulcers; only in advanced cases are the internal organs affected. The diagnosis is readily confirmed by microscopic examination of a smear from an ulcer or a nodule, which will show the acid- and alcohol-fast bacillus of the disease in enormous numbers, and mostly in the cells. It is doubtful that the bacillus has ever been cultivated.

Currie has shown that rats may infect each other by contact, also that bacilli of rat leprosy may often be demonstrated in the heart's blood of infected rats.

Marchoux (1923) inoculated rats with the spleen tissue from a man with a leprosy-like condition and produced a disease in rats indistinguishable from their spontaneous leprosy. Further studies upon rat leprosy will throw light upon the modes of transmission and control of the human disease.

**Contagiousness.** In the Philippines (Doull and others, 1942), a substantial

proportion of persons exposed to lepromatous leprosy in the household contract leprosy before the age of 25 years, 29 per cent of males and 14 per cent of females. Of persons without a history of family contact, in the areas studied, less than 6 per cent of males and less than 3 per cent of females contract the disease before age. It follows, therefore, that the disease, in the Philippines at least, is of a higher order of contagiousness than has been thought, but probably is much less so than is tuberculosis. Contact with the tuberculoid type apparently does not involve material risk of infection. There is no evidence that the disease is inherited; children born of leprous parents rarely develop the disease if removed at once.

Doctors, nurses, sisters of charity, ward tenders and others directly exposed to leprosy sometimes become infected. Notable examples have been Father Dan of Molokai, Hawaii; Father Bagliolo in New Orleans; Sir George Turner in Pretoria and Mary Reed in India. The influence of exposure is clear in cases among veterans of the United States Armed Forces. Of 32 American veterans of the Spanish American War who developed the disease 19, and of 55 World War I and Korean War veterans, 15 were born in northern states. In World War I, on the other hand, there was little exposure; none of 51 veterans admitted to Carville was born in a northern state.

Geographic location is a dominant factor in the spread of leprosy, although the disease has occurred in every climate. In the United States it propagates chiefly in south Florida, southeastern Texas and southern California. Why leprosy spreads in some regions and not in others remains unsolved.

**Modes of Transmission.** Leprosy is apparently a contact disease, but just how it is caught we do not know. The prevailing notion is that the bacilli invade the body through the skin or mucous membranes. The bacilli may leave the body in sputum or in its secretions or excretions. They are contained in enormous numbers in discharges from broken-down nodules of the skin or mucous membranes. As the nose is often affected, these discharges may be infectious. Even feces and urine contain acid-fast bacilli.

In view of the doubt concerning the way the leprosy bacillus enters the body, the different possibilities deserve consideration. The site of the lesions, the course of the disease and the higher prevalence in the tropics suggest that the bacilli enter through the skin. It is also possible for them to enter through the mucous membranes of the nose or throat, or through the digestive tract. Food has been accused; insects are suspected.

It may be definitely stated that leprosy is not due to the eating of any particular food. Jonathan Hutchinson stoutly maintained that leprosy was due to a fish-bone, but there is no satisfactory evidence in favor of the fish theory, and much against it. One thing is plain, and that is, leprosy is not contracted from any of the known animals, but is an infection which passes somehow rather directly from man to man.

The suspicion that parasitic insects may play some role in the transmission of leprosy has existed for some time, but the evidence bearing on the possible role of insects in the transmission of leprosy is based upon analogy and is largely presumptive. The final verdict will depend upon further studies.

A majority of lepromatous patients at some time in the disease have acid-fast bacilli in their nasal secretions. The importance of the nose in leprosy was brought into prominence at the First International Leprosy Conference in 1897 by the work of Sticker, who made sweeping statements concerning the nose as the site of primary lesion and the danger of nasal secretions in transmitting the disease. J. Selme and Laurans in 1895, Gerber in 1901, Werner in 1902 and Sheroux in 1903 and others have shown the frequency with which the bacilli of leprosy appear in the nasal secretions.

\* There are many acid fast bacilli, and we have no clear criterion to differentiate the bacilli of leprosy, except that it cannot be cultivated on laboratory media.

nasal secretions and the importance of the nose as a site of leprous lesions. Brinckerhoff and Moore, however, who made a careful study of this question in Honolulu, point out that most of the studies upon the importance of the nose in leprosy have been made upon relatively advanced cases. They found the nose frequently the seat of infection when the disease is well developed, but practically never as a primary incipient lesion. If there be a primary lesion of leprosy it has not been discovered. Brinckerhoff's view that nasal lesions are frequently primary has not been confirmed.

Jeanselme in 1914 reported observations supporting the Chinese and Japanese belief that leprosy spreads largely by sexual contact, but there is little evidence to support this view.

It is sufficient for practical purposes to know that the disease appears to be spread by direct contact especially under conditions of overcrowding, particularly where there is close and protracted association between lepromatous patients and young children.

**Prevention.** In view of the unsatisfactory nature of our knowledge of the transmission of leprosy, it is not surprising that our efforts at control and prevention have not been crowned with conspicuous success. The key to the attempts at control of the disease has always been isolation of the patients. That this has not proven highly successful probably is due to the fact that under practical conditions the cases are not brought under observation and isolation until the disease is somewhat advanced. This is to be accounted for by the insidious onset and by ignorance on the part of the patient as to the nature of the early manifestations of the disease and to the disinclination to surrender to health officers since this usually means separation from home and associates.

The defects of isolation as it is practiced have led to certain modifications in the handling of leprosy. Home segregation, in which the patient is confined to his domicile and even then kept from contact with children, and the establishment of outpatient clinics where patients report periodically for examination and treatment, are now advocated.

It is obvious that in countries where the disease shows no tendency to spread, stringent measures are not required such as are desirable in endemic areas.

There is difference of opinion concerning the value of segregation. Sir Leonard Rogers believes that it is effective even when imperfectly carried out; Newman, Hutchinson and others hold that the disease disappeared in Europe despite segregation. The effect doubtless varies with the proportion of lepromatous patients segregated. Segregation in the Philippines probably so far has had no conspicuous effect upon the prevalence of the disease; the results however, are the subject of controversy. There are factors in the control of leprosy not yet understood.

There can be little objection in a country such as ours, where leprosy shows slight tendency to spread, to give a patient his freedom, except in the endemic foci in the Gulf States. There is no more danger from a leprosy patient with clean personal habits, who exercises care concerning the discharges from the lesions, than there is from an open case of tuberculosis of the glands of the neck. The purely nerve cases may properly be given a greater degree of liberty than those with nodular manifestations. The parole system, begun in 1912 in the Hawaiian Islands, is sensible and successful. Those paroled are required to report for examination from time to time.

Under the immigration law aliens with leprosy are excluded from admission to the country. Under Federal quarantine regulations, United States citizens having leprosy upon return from a foreign country may be detained until arrangements can be made for safe travel or isolation, subject to state and local health laws. Aliens who arrive with leprosy, or who are found to have entered the country while

they had the disease, should be reported to the Immigration and Naturalization Service, since they may be subject to deportation.

Practical methods for the control of leprosy in localities in which it shows tendency to spread may be summed up as follows:

1. Educational measures directed toward early recognition.
2. Facilities for specialist consultation and bacteriologic diagnosis.
3. Notification to the local health authority.
4. Immediate isolation of lepromatous patients, preferably in a leprosarium.
5. Home isolation, with clinic supervision, is necessary in many countries.

Dependence must be placed upon educational measures, sulfone treatment, disinfection of discharges, and, wherever possible, removal of young children from the home. Infants should be removed at birth.

6. An examination every six months of all household contacts and close associates to detect new infections at the earliest moment.

**Specific Prophylaxis.** Vaccination with BCG induces reactivity to leprosy and thus may be of value in prevention of the lepromatous type.

**Treatment.** Drugs of the sulfone group, first used in 1941 by Faget and his associates at Carville (Faget, 1946), are rapidly replacing chaulmoogra oil in the treatment of leprosy. Beneficial results are attributed to a radical common to the group, diaminodiphenylsulfone. Prolonged administration is required. After three years only about 30 per cent of patients are negative bacterioscopically, but practically all patients continuing treatment for five or six years show substantial benefit. Experience is as yet too short to judge whether cases are cured or merely arrested.

In appraising the influence of treatment it must be borne in mind that leprosy, particularly of the tuberculous type, is prone to prolonged periods of quiescence and that marked improvement may occur spontaneously, and indeed this may lead on to apparent cure.

### INFECTIOUS MONONUCLEOSIS

(*Glandular Fever, Pfeiffer's Disease*)

Infectious mononucleosis is a relatively benign acute or subacute infectious disease of unknown cause having a diverse and somewhat obscure clinical pattern. After an incubation period of from 5 to 15 days, the onset is rather abrupt with fever and constitutional symptoms, general malaise, mild prostration and headache. Usually there is sore throat and within two or three days enlargement of the lymph nodes becomes apparent. While the cervical nodes may be especially prominent, enlargement usually affects all the nodes of the body. This gives a lead to the diagnosis, but is not always manifest, particularly in adults. In some cases there may be little or no inflammation of the throat; in others, it may be sufficiently severe

lead to membrane formation. About 15 per cent of cases show a skin eruption at the onset, which has been variously described as purpuric, maculopapular, morbilliform or scarlatiniform. The duration of the fever is commonly not more than five days. The enlargement of the lymph nodes reaches a maximum at the time the fever is subsiding and subsides with convalescence. Recovery is usually complete in from 10 days to 3 weeks, but in some patients it may be a matter of several months. Occasionally, the illness is complicated by jaundice, and in a larger proportion functional tests indicate liver damage (Jordan and Albright, 1950), giving rise to confusion with "infectious hepatitis."

**Laboratory Diagnosis.** As the name implies, a characteristic feature of infectious mononucleosis is a hematologic change. In the early stages there may be a leukocytosis or even a leukopenia. Later, a mononucleosis develops, the total white cell count rising to 15,000 or more, with both a relative and absolute increase in lymphocytes. Some of these are large monocytes, originating in the reticulum of lymphatic tissues, with a peculiar morphology. The discovery in 1932 by Paul and Bunnell that the serum of patients with infectious mononucleosis agglutinated suspensions of sheep cells in high titer provided a test of value in confirmation of the diagnosis. The test for the presence of this heterophile antibody usually becomes positive between the sixth and twenty-sixth days of the illness, most commonly between the twelfth and twenty-first days. It usually remains positive for from two to four months after onset, although this period varies greatly. A sheep-cell agglutination in a dilution of 1:32 or greater with the Paul-Bunnell technic is considered significant. A negative reaction does not rule out the diagnosis, nor does a positive one definitely establish it. If the titer is high enough (1:128 or more), sheep-cell agglutinins in normal serum, in serum from patients with serum sickness and other conditions, can be differentiated by prior absorption with guinea pig kidney and boiled beef cells.

**Prevalence.** Attempts to transmit infectious mononucleosis to rabbits, monkeys, white mice, guinea pigs and human beings have failed. Nevertheless, observations on the occurrence of the disease led to the inference that it is contagious under some circumstances—not as yet well understood. The disease occurs sporadically and in propagated epidemics. Sporadic cases do not appear to be very contagious, for hospitals treat these patients in an open ward without cross infection. Rarely can one case be traced to contact with a preceding case. Since West's report of an outbreak in an Ohio community in 1896, many accounts have appeared of similar epidemics in mental institutions, boarding schools, children's hospital wards, and in military camps. In recent years, infectious mononucleosis has been an important source of admissions to hospitals and infirmaries of colleges and universities. At Dartmouth College it represented 0.74 per cent of the total infirmary admissions (Milne, 1945); at Harvard University 1.5 per cent (Contratto, 1944); and at Yale University 1.7 per cent. At Smith College it accounted for 0.78 per cent of admissions in 1945-46 and by 1948-49 this had increased to 3.4 per cent (Evans and Robinton, 1950). No general seasonal trend is apparent. While the data suggest that transmission may be effected by subclinical or inapparent infections, the evidence in this regard is not entirely clear, owing to the uncertainties of identification by laboratory procedures. When medical students are required to do differential blood counts on themselves, it is surprising how frequently they are found to have mononucleosis and a positive Paul-Bunnell test in the absence of definitive clinical symptoms.

## TRACHOMA

Because of its progressive disfiguring and incapacitating character, trachoma has always been the most important of ocular infections. It is still a problem of considerable magnitude among the poor neglected populations of Egypt and the Middle East, countries bordering the Mediterranean, Russia and the Orient. In the United States, the incidence of trachoma has never been accurately determined, since the disease is not uniformly reportable. It has been endemic for years in the native population of West Virginia, Arkansas, Tennessee, Oklahoma, Ohio, Kentucky, Missouri and Illinois. This is the so-called "trachoma belt." Cases are by no means limited to this area. New cases of trachoma, exclusive of those among Indians, are shown in Table 5-3, by states of origin as reported to the U. S. Public Health Service in 1937 and 1941. The figures probably do not represent an actual increase in the incidence of trachoma but a better appreciation of its presence and better reporting methods (Forster and McGibony, 1944). The first recorded survey of trachoma among Indians was made by the U. S. Public Health Service in 1911. It was found that 22.7 per cent of a group of 39,231 Indians examined on various reservations in the United States were found to have trachoma. The incidence varied from 68.72 per cent in Oklahoma, the highest, to none found in the Indian Territory, Florida. Incidence throughout the years following maintained a fairly constant average of 18 to 25 per cent. No appreciable progress was made in combating the disease until 1939, although thousands were treated by surgical and medical means. Incubation period is 5 to 12 days, determined by human volunteer experiments.

In the early stages, it is differentiated with difficulty from other forms of chronic follicular conjunctivitis. The first visible evidence of the disease is the presence of follicles beneath the conjunctiva of the upper and lower retrotarsal folds. Slight changes in the upper limbus region make diagnosis possible at this early stage. Later, follicles may be found on the palpebral and the bulbar conjunctivae. The inflammatory process involves the cornea, particularly of the upper limbus region. During this acute stage the exudate may be abundant and mucopurulent in character. This becomes scanty as the process subsides over the course of several weeks, but conjunctival and corneal cicatrization may progress. In the advanced stage, deformity of the eyelids with cicatricial entropion may develop and vision be impaired by the scar formation from pannus (extension of blood vessels from the upper limbus downward into the cornea) and recurrent ulcers. The condition may become arrested at any stage and healing take place.

**Etiology.** The disease has been transmitted experimentally to human beings and other primates, notably apes, baboons and monkeys. Unfortunately, the disease in experimental animals is self limited, appears only as a follicular conjunctivitis and does not develop pathologic changes characteristic of human trachoma, i.e., pannus and scar formation. In 1907, Halberstaedter and Prowazek discovered intracellular clumps of minute bodies in tissue scrapings derived from cases of trachoma studied in Java. They thought that the structures they had found were the etiologic agent of trachoma.

In 1934, Thygeson concluded that the HP inclusion bodies represented intracellular colonies of a virus in different stages of development. Later, Thygeson and Proctor proved that the virus of trachoma was readily filtrable through colloidal

membrane. The virus dies rapidly outside the human body, and is easily destroyed by heat. Attempts to cultivate it in tissue culture and on embryonated hen's eggs have been unsuccessful. Studies of Rake and others (1942) suggest that antigenic components are shared between the virus of trachoma and the members of the lymphogranuloma-psittacosis group of agents. Laboratory confirmation of the diagnosis is based on the finding of typical cytoplasmic inclusion bodies and on characteristic cytologic changes in expressed follicular material (Julianelle, 1938).

It is believed that the infectious agent is transmitted from eye to eye by means of contaminated fingers or articles. In sporadic cases, it is often impossible to trace a source of infection. In countries where trachoma is widely prevalent it may be acquired during infancy. Its transmission is probably facilitated in these areas by the occurrence of epidemics of acute infectious ophthalmias due to other causes. The prevalence of trachoma is associated with poor hygienic conditions, crowded living and poor nutrition.

**Control Measures.** Prior to 1938, trachoma was treated by a combination of medical and surgical means. Where this was available it brought relief from symptoms and arrested the progress of scarring. However, these measures were ineffective in reducing the incidence of the disease. A number of workers have reported favorably on the use of sulfonamides, given orally, parenterally or locally (Thygeson, 1945). Under sulfonamide therapy the prognosis of trachoma has changed entirely, and in early cases cures can now be expected in a matter of weeks. It is ineffective, however, in the late stages, when surgical intervention becomes the only means of relief. In the United States prior to the introduction of sulfonamides in 1938, the extension of antitrachoma campaigns conducted in the Indian schools were showing only partial success; as a result of sulfonamide therapy instituted at that time, the incidence of the disease has been strikingly reduced as indicated in Table 5-4.

Recent reports indicate the tetracycline antibiotics or chloramphenicol are equally effective. When active lesions exist, children should be excluded from school.

Table 5-4. Examination of school children for trachoma

## ARTHROPOD-BORNE DISEASES

### MALARIA

GILBERT F. OTTO, Sc.D.

Malaria is really a closely related group of diseases caused by four different protozoan species, *Plasmodium vivax*, *P. ovale*, *P. falciparum*, and *P. malariae*. Although these diseases differ one from the other biologically, pathologically, clinically, and epidemiologically, there is a common core of similarity among them so that the group may be conveniently discussed as a unit. The characteristic clinical manifestations of malaria are those resulting mainly from the recurrent, intermittent, remittent, destruction of erythrocytes or the sequelae of such destruction.

Although malaria has been known since antiquity and the early Greeks and Romans appear to have associated "the intermittent fevers" with the swamplands during the summer, it was not until the latter part of the past century that there was any definite clue to the nature of that association. Laveran, in 1880, was the first to describe *Plasmodium* in the blood of malarious patients, and shortly thereafter Manson developed his mosquito theory of transmission; it seemed to Manson a reasonable postulate that mosquitoes became infected by feeding on the malarious patient and then disseminated the infection in the water as they died. Under Manson's stimulus Ross, in 1897, 1898 and 1899, demonstrated not only that mosquitoes became infected by feeding upon malarious individuals but that the parasite underwent an obligatory development (sporogony) in the mosquito host and, transcending Manson's theory, demonstrated in the case of a bird malaria that it was thereafter transmitted to the next individual as the culicine mosquito fed again. Ross's discoveries were quickly confirmed by a number of workers, including Koch, who had early subscribed to the "mosquito theory." Bignami, Bastianelli, and Grassi not only confirmed Ross's findings but worked out further details of development of the infection in the mosquito and, in 1898, were the first to actually demonstrate the transmission of malaria to man by the bite of the infected anopheline mosquito. Manson, in 1900, produced the infection in volunteers in London who were bitten by anopheline mosquitoes which had been infected by Bastianelli in Italy, and, in the same year, three of Manson's colleagues lived in a screened hut during the malaria season in the Roman Campagna without contracting malaria, while the local population in unscreened houses suffered severely.

Thus, by the turn of the century, it seemed simple enough to eradicate or, at least, reduce and control "the scourge of the tropics" by the simple expedient of eliminating or reducing the mosquito population. Despite some skepticism, plans were enthusiastically discussed, and some were actually launched in various parts

of the world. The outstanding early success was that which attended the efforts of Gorgas and his staff. Although the daring and thoroughness of this program is commonly remembered and cited in relationship to the dramatic effect upon yellow fever, it was equally successful against malaria. First in Havana, Cuba (between 1901 and 1904), and later in the Panama Canal Zone, the annual attack rate of approximately one case per inhabitant dropped in a few years to a few dozen per 1,000 as the transmission of malaria by *Anopheles albimanus* was interrupted. Larval breeding places were filled, drained, or periodically treated with oil; adult mosquitoes were killed in houses and known cases were isolated behind screens for treatment. In the Federated Malay States, Watson was equally successful in eliminating malaria by destruction of anopheline breeding sites. Clearing the jungle and draining the swamplands near the town of Klang eliminated *A. umbrosa* and freed the town of malaria.

Elsewhere in the world various lesser degrees of success, and even failure, resulted from similar efforts. In the meantime, malaria in Europe was gradually receding to its Mediterranean stronghold without any appreciable attempt at control, leaving in its wake isolated pockets of persistent malaria, as, north Holland, which showed no signs of yielding to the most persistent frontal attack by health agencies. Anopheline reduction in north Holland had no demonstrable effect upon the prevalence of malaria, and, conversely, elsewhere there was no discernible diminution in anopheline mosquitoes associated with the rapidly receding malaria. Experiences in World War I were discouraging. Whole armies, both Allied and Teutonic, were immobilized by malaria in southeastern Europe during 1916, and returning personnel after the war provided the seed for severe epidemics of malaria in northern Europe. The disease even extended into the Arctic, at Archangelsk. Again, however, it spontaneously disappeared from some areas and gradually receded southward through most of Europe; and again without any evident decrease in the anopheline population. Thus, the enigma of "anophelism without malaria" became a challenge, almost a battle cry, to the frustrated malariologist.

Even the apparent success of the antilarval measures and screening of houses in some parts of the southern United States was not without its ambiguities. The League of Nations Malaria Commission, which visited the United States in 1926, noted that the disease had a definite downward trend, had already disappeared from large areas, and seemed to have reached a point at which it was of very little importance as a cause of sickness and death before the initiation of antimosquito campaigns. As in Europe, there was no appreciable diminution of *Anopheles* in the areas where malaria had disappeared and the decline of the malaria rate was not accelerated in local situations with intensified efforts at mosquito control.

Furthermore, it was soon recognized that conditions in Europe and North America were vastly different from those in many tropical areas and it became equally evident that within the tropics there were marked differences in the epidemiology of the disease; that, for instance, rural malaria in the foothills of the Philippines must be handled differently from urban malaria in Calcutta. Nevertheless, the net result was to cast a great deal of doubt on the value of the early magic formula "reducing malaria by antimosquito measures." Thus, the Second General Report of the Malaria Commission of the League of Nations in 1927, while recognizing the "limited value of antilarval measures," stressed the value of "sanitation" and

ect measures. James, Swellengrebel, and others advocated the liberal use of quinine which would reduce the duration and severity of the illness, although it could not be expected to reduce the attack rate. The destruction of mosquitoes, particularly swatting blood-engorged mosquitoes, resting in houses was the only antimosquito measure which appeared to offer any prospect of immediate value in control, at least in Europe. It was pointed out that bonification, i.e., improved housing, farming practices, and general living, had done more in the temperate zones to reduce malaria than all the antimosquito measures combined. The resulting confusion was aptly discussed in 1937 by Hackett in the first chapter of his book (*Malaria in Europe*) under the title "A House Divided." In 1936, Russell noted that, although measures were available for malaria control in organized communities, such as cities, "the longer one observes malaria in the tropics the more one is forced to conclude that, so far as the average rural areas are concerned, the problem of control is still unsolved."

The League of Nations Malaria Commission in its several reports during the 1920's and 1930's echoed the sentiment of some malariologists that the discovery of the insect vector of malaria had not solved the problem of malaria control; that intensified research on all phases of malariology was still needed to provide the answers. Investigations were already in progress the world over, and the attack continued with renewed vigor through the late 1930's, World War II, and the post-war period. The life history of the parasites and their bionomics in both the insect and vertebrate hosts and the host responses to infection have been critically studied in the laboratory; the mode of attack of old and new therapeutic agents against various stages of the infection, the basic pharmacology of these agents, and their relative values in mass treatment and suppression have been investigated. Of fundamental importance in control has been the detailed information garnered on the recognition and biology of different species, and subspecies, of *Anopheles*, with particular reference to their relative roles in transmission of malaria. Evaluation of control projects and field studies over the past half century helped significantly in clarifying the confusion.

It is safe to say that in the half century since the discovery of the mosquito transmission of malaria the pendulum has completed an arc from (1) Ross's and Manson's "malaria control through destruction of mosquitoes" and Grassi's "modification" through the destruction of *Anopheles*, (2) to the point where, in 1927, the League of Nations Malaria Commission "considers the treatment of malaria-infected persons to be one of the most important measures even from the point of view of prevention," (3) back to major emphasis on antimosquito measures. In the intervening years the formulae have been further sharpened to "species control" and "species eradication." Thus, the attack is directed not against anophelines in general but against that species, or those species, which within a given area are most likely to be the principal vectors of malaria. Furthermore, with the development of effective use of residual spraying, antilarval measures have been largely abandoned in favor of attacking the adult female in human habitations where it commonly transmits malaria.

**Distribution of Malaria.** Despite the fact that significant malaria control, and even eradication, has been accomplished in some areas, malaria still remains the single most common cause of debilitation and death throughout the world. In addi-

tion to the early successes in eliminating malaria in local situations such as Havana, Cuba, the Panama Canal Zone, the town of Klang in Malaya, from the "fish po areas" of Java, and the more recent elimination of "*gambiae*-transmitted malaria" from Brazil, the past decade has seen similar successes over much wider geographical areas. The natural recession from "bonification" accompanied by intensive control procedures appears to have eliminated endemic malaria from the United States (Symposium on Malaria Eradication, 1951). Measures of attack have all eliminated malaria from Chile, British Guiana, Venezuela, Sardinia, and parts of western Europe.

Nevertheless, malaria is still one of the important health hazards in so many areas of tropical America, southeastern Europe, and Asia Minor. In much of tropical Africa, southern Asia from India to China, and the western Pacific Islands as far north as Formosa, malaria continues undiminished by control measures. It has been estimated that over 300,000,000 people still suffer from malaria and over 3,000,000 die annually from the disease or its complications. Thus, between 5 and 10 per cent of the world's population appear to suffer from malaria. It is still the most prevalent disease in many of the tropical areas of the world and in the temperate zone of Asia.

Malaria is absent, and apparently has never occurred, due to the absence of anopheline mosquitoes, in the North Pacific east of the Philippines and the South Pacific east of the 175th meridian. This includes such groups of islands as Maria, Caroline, Marshall, Gilbert, Ellice, Fiji, Samoa, Tokelau, Hawaii, and Marquesas. In the Western Hemisphere such tropical islands as the Bahamas and the northern Leeward Islands are similarly free of anophelines and malaria.

**Life Cycle of the Malaria Parasite.** The sexual development (sporogony) of the plasmodia of man is completed with resulting multiplication only in anopheline mosquitoes.\* Asexual multiplication (schizogony) takes place in two distinct phases in man, the commonly known development in the red blood cells and the little known but apparently more basic development in other tissues (the so-called erythrocytic or E E stages). The sexual cycle is initiated in man with the product of the male and female elements (microgametocytes and macrogametocytes).

The gametocytes, ingested with the blood meal, undergo maturation within a few minutes in the stomach of the mosquito. Each macrogametocyte produces a macrogamete, or female cell, which is fertilized by one of the (2 to 8) microgametes or male elements, which escape from the microgametocyte. The resulting fertilized cell (zygote) soon elongates into a motile ookinete which penetrates the stomach wall by slow amoeboid movement and comes to lie under the parietal lining of the stomach, where it rounds up and secretes a protective membrane to become an oocyst. Within the oocyst, nuclear and cytoplasmic divisions produce a number of sporoblasts which, in turn, develop rosettes of sporozoites. A few hundred to several thousand sporozoites are thus produced which upon rupture of the oocyst migrate through

\* So far as is known, the sporogony of other species of mammalian plasmodia also takes place only in anophelines. The one report of the development of the plasmodia of man in culicine mosquitoes has never been confirmed and appears, at any event, to have no epidemiological significance. However, the avian plasmodia appear to be commonly, if not principally, transmitted by culicine mosquitoes, although a number of avian species readily develop in anophelines.

body cavity. Within two to three weeks, depending upon a number of factors such as temperature, humidity, and species, the sporozoites arrive in the salivary glands ready to infect the next human the mosquito bites.

The early development in man is entirely unknown but it is clearly established that the *sporozoites do not develop in the red blood cells*. The pioneer work of Huff with *P. gallinaceum* of chickens has shown that the sporozoites develop into large schizonts in cells of the reticulo-endothelial system and this has subsequently been found by a number of workers to be the case with several other species of malarian plasmodia. Huff and Colston have shown that the merozoites resulting from the second generation of these pre-erythrocytic or exoerythrocytic schizonts are capable of penetrating erythrocytes and developing into the well known erythrocytic schizonts. Thereafter, both erythrocytic and exoerythrocytic schizogony may continue.\* Whereas the erythrocytic schizonts produce a dozen or two merozoites the pre-erythrocytic schizonts produce from less than 50 merozoites in *P. relictum* to over 500 in *P. gallinaceum*.

Shortt and his co-workers (1951) have reported very large pre-erythrocytic schizonts of *P. falciparum* in the parenchyma cells of the liver as early as the fourth day after infection and of *P. vivax* as early as the sixth day. The continuity between the sporozoites and these reported schizonts in the parenchyma cells and between these forms and the blood stages have not been traced directly. Certain questions have been raised which will undoubtedly be resolved by further experimental observations. Regardless of the details, it seems certain that these or similar pre-erythrocytic stages occur and account for the failure of attempts at chemical prophylaxis. Shirley has failed to demonstrate parasites of *P. falciparum* in the general circulation in less than six and a half days after the mosquito bite and *P. vivax* in less than seven days, even by the subinoculation of 200 ml. of blood into susceptible volunteers. Even in very heavy initial infections parasites cannot be detected in the blood by the usual technics (examination of either thin or thick blood smears) until some days later.

It appears likely that the exoerythrocytic development of *P. falciparum* and *P. ovale* is much more limited than is the case with the other two species. Since relapses are uncommon with the two former species it is possible that exoerythrocytic schizogony often terminates during the primary parasitemia. With both *P. vivax* and *P. malariae*, however, the exoerythrocytic schizogony appears to continue for years and to be the source of the recurring parasitemia with resulting clinical relapse.

Each cycle of schizogony in the red blood cells requires about 48 hours for *P. vivax* and *P. ovale*, 24 to 48 hours for *P. falciparum*, and 72 hours for *P. malariae*. Each schizont of *P. vivax* produces 12 to 24 (commonly 16) merozoites; *P. ovale* about 8, *P. falciparum* 8 to 24 (as high as 32 have been reported), and *P. malariae* about 12 (commonly 8). The merozoites of *P. vivax* and *P. ovale* have a predilection for reticulocytes and usually invade and develop in these large young cells. Schüff-

\* Huff and Colston have termed the first generation of pre-erythrocytic schizonts, which develop from the sporozoites, *cryptozoites* and the second generation *metacryptozoites*. The exoerythrocytic schizonts which may be initiated later by merozoites from the erythrocytic cycle they term *phaenerozoites*. The relationship between phaenerozoites and continued generations of metacryptozoites is not clear.

ner's dots are characteristically seen in the parasitized cells in these infections, appearing earlier and more dense in *P. ovale* infections. *P. falciparum* and *P. malariae* show no such marked preference for reticulocytes and are more commonly seen in mature normal-sized erythrocytes; Schüffner's granules are not associated with the species. With all species, except *P. falciparum*, all stages of erythrocytic schizogony from the newly established merozoite or young trophozoite (ring stage) to the mature and rupturing schizont are seen in the red blood cells in the peripheral circulation. Only the young stages (rings) of *P. falciparum* are characteristically seen in blood smears; developing forms and mature schizonts are seen only in hepatic infections, commonly when the patient is in a critical condition. Ordinarily, the erythrocytic schizonts in this disease may be in the vascular bed of internal organs or adherent to the vascular wall and do not flow with the blood.

Under circumstances not clearly defined, some of the merozoites develop into gametocytes rather than schizonts. This occurs both early and late in the infection but, in general, the ratio of gametocytes to schizonts increases in the course of infection. It is commonly assumed that gametocytes develop from merozoites of erythrocytic schizogony but it has not been established and there is evidence in *P. gallinaceum* infection that they develop from merozoites arising from exoerythrocytic schizogony.

**The Disease.** The incubation period varies, not only with the species and strain of malaria, but with the number of sporozoites in the infecting dose. In general, however, the incubation period of *P. falciparum* is around 9 to 11 days, *P. vivax* and *P. ovale* about two weeks, and *P. malariae* three to four weeks. Parasitemia (patency) detectable on thin or thick smear examination, usually occurs a day or so before the first clinical evidence of disease. Prodromal signs include headache, general malaise, and a temperature of 100° F or higher followed in a day or two by the typical malarial paroxysm. With *P. vivax*, *P. ovale* and *P. malariae* there is usually an intermittent fever with the paroxysms sharply defined, approximately every 48 hours for the first two species and 72 hours for the latter. The mu-  
described rigor or subjective feeling of chills is associated with a rapid rise in temperature which may reach 104° F or even higher in less than an hour after it goes above 100° F. Chills are reported to occur in well over half of the paroxysms; when the temperature is less rapid there may be no evidence of chills. The temperature is above 100° F for 9 to 12 hours. In general, the temperature is highest but the febrile period shorter when it rises rapidly enough to produce chills. *P. falciparum* characteristically produces a remittent fever. Anemia develops in malaria most rapidly in *P. falciparum*, often with a net loss of 60 per cent of the erythrocytes scarcely over a week. Splenic enlargement is a constant characteristic of all malarias. In the primary attack, the acute splenic tumor may even noticeably fluctuate in size with paroxysms. In chronically repeated malaria, or repeated exposure to malaria, the spleen will become fibrosed and may ultimately become permanently enlarged. The many reports of reduced liver function in both primary and relapsing malaria may, perhaps, be explained by the reports that the pre-erythrocytic stages develop in the liver.

There are many localized manifestations of malaria which are a source of confusion. These are usually associated with *P. falciparum* infection. Among these are cerebral malaria, and algid, or "cold," malaria, which is frequently associated with

sclerotic manifestations, are often associated with fatal malaria. Cerebral malaria is particularly associated with a high mortality rate. Uncomplicated infections with the other three species rarely prove fatal but *P. vivax* is associated with protracted disability and is a significant contributory cause of death.

Cachectic malaria is associated with repeated attacks of malaria in individuals suffering from some concurrent debilitation, frequently malnutrition, hookworm, or both.

*Blackwater fever or hemoglobinuric fever* is a complication in highly malarious districts. It, too, is associated with *P. falciparum*. It occurs only after repeated attacks of malaria over a period of a year or two. The red cells become friable and intravascular hemolysis occurs. The renal tubules are blocked and the kidney pathology appears to be a secondary rather than a precipitating cause. Inadequate treatment of recurring malaria appears to be an important precipitating cause.

**DETECTION OF MALARIA IN THE INDIVIDUAL.** The final diagnosis of malaria usually rests upon the finding of the malaria parasites in the peripheral blood. For this purpose both the thick and the thin blood smears are of value. The regular thin smear used in differential leukocyte counts is of value because the species of parasite can be more easily determined when the cell and the parasite within it are both intact. Any of the Romanovsky stains are suitable, but malariologists generally prefer Giemsa's or Leishman's stains since they give more critical staining of the parasites than some of the other blood stains. Thick smears have the advantage of concentrating the blood and thus increasing the chance of finding parasites. Such a smear is usually made about the size of a dime from blood which "wells up" freely from a finger prick. The blood should be stirred a few seconds with a corner of a glass slide and should finally be about two to six cells deep. If the smear is too thick it will chip off on drying. The blood cells may be lysed and the parasites stained at the same time by immersing the dried smears for 45 minutes to an hour in a 1:50 dilution of Giemsa's stain buffered at pH 7.0 to 7.2. Recently, Donaldson and Crooke (1950) have shown that some parasites will be washed off these slides if they are immersed vertically, and will float up to the surface film where they may lodge on other slides stained at the same time or later. Thus, when many slides are stained at the same time or in rapid succession it is desirable to add a few drops of Triton X-30 (30 to 33 per cent Triton X-100) to reduce the surface tension. When only a few slides are stained at a time it may be simpler to lyse the cells in fresh distilled water and thereafter flood the smear with concentrated Giemsa stain.

Field's method of staining thick smears is more rapid and is beginning to find favor in some quarters. The blood cells are lysed by immersion for a few minutes in distilled water and then the parasites are stained by immersing the smear in a solution of Azur-B for a second and then for the same time in eosin. Recent modifications include reversing the order of staining. Excellent smears are obtained by experienced personnel but the results are less certain in the hands of inexperienced technicians.

Parasites are not continuously present in the peripheral blood even during the primary attack and may be much more sparse during relapse. Thus, in cases of suspected malaria it may be necessary to examine as many as two or three smears taken at 12-hour intervals before parasites are demonstrated.

Parasites may be found in bone-marrow smears but the technic is apparently

not sufficiently more delicate than the use of thick smears of peripheral blood justify it as a routine procedure.

Numerous attempts have been made to develop a serological test for malaria without significant success so far. It may be noted, however, that serological tests for syphilis may be positive during the primary attack of malaria or even late in incubation period of malaria in nonsyphilitics.

**DETERMINING THE INDICES OF PREVALENCE.** Morbidity and mortality records and even less well defined history of malaria can serve as a preliminary guide to the scope of the problem. A more definite indication of the problem and evaluation of control procedures, however, is obtained by direct examination. The two indices which are most useful for this purpose are the Spleen Index and the Parasite Index. The two together give a higher figure for malaria prevalence than either alone. The best correlation between the two indices is obtained from young children during the season of greatest transmission and the poorest in adults during the off-season. Evidence on the extent of the malaria problem can be obtained by determining spleen rate and parasite rates in any and all age groups. However, neither rate in the adults of the indigenous population provides a satisfactory measure of the amount of current transmission. Children, particularly those from two to five years of age, provide a better measure of current transmission. In the temperate zone these rates should be obtained in the summer. In the tropics, it may be desirable to obtain such rates periodically to determine whether or not there is a marked seasonal change in transmission rate.

The spleen rate can be more rapidly obtained than the parasite rate. A quantitative measure of spleen size in children will be of further value in determining the degree of malariousness. Hackett and Russell appear to prefer the following grades as a measure of spleen size.

- 0—Normal, nonpalpable.
- 1—Palpable on deep inspiration only.
- 2—Palpable on normal inspiration, not projecting more than half way from costal margin to a horizontal line through the umbilicus.
- 3—Projecting to the level of the umbilicus.
- 4—Projecting half way from the umbilicus to a line through the symphysis pubis.
- 5—Projecting lower than those in group 4.

Since the limits placed on the classes defined above are not standardized or universally accepted, it is important to record a definition of classes used. Boyd, for instance, would insert a class between the above classes 1 and 2, i.e., palpable on normal inspiration but not projecting below the costal margin; he would, however, combine the above classes 4 and 5 into one class.

A value for the average enlarged spleen (AES) is obtained by multiplying the number of spleens in each class by the class number and dividing the sum of the products by the number of individuals examined. Russell favors the use of both the AES value and the percentage of persons with enlarged spleens as a combined spleen index. Regardless of what method of computation is used, it is desirable to record the number (or percentage) of spleens in each class.

Splenic enlargement occurs with a great many infections and with some degenerative diseases but, for the most part, these possible complications do not serio

interfere with the use of the spleen size as an index of malaria within endemic areas. However, such diseases as kala azar, bartonellosis, and schistosomiasis may produce efficient chronic enlargement of the spleen to complicate the picture. Thus, if for any other reason, it is desirable to determine the parasite rate on at least a portion of the juvenile population during the season of most active transmission. The examination of blood smears for parasites has the further advantage of permitting the determination of the species of plasmodia involved.

**Factors in Transmission.** The older concept that malaria resulted from the presence of mosquitoes and human gametocyte carriers, or the refinement that it resulted from anopheline mosquitoes, human gametocyte carriers, and susceptible humans, does little more than define the minimum requirements for active transmission of the disease. The malaria problem of a community, both the level of endemicity and the frequency and severity of its epidemics, is the function of a variety of often conflicting dynamic forces. Russell in 1931 expressed the complexity of these interacting forces in a formula:

$$(x + y + z) \text{ bepti} = \text{malaria prevalence}$$

where:  $x$  = the human gametocyte carrier

$y$  = the anopheline vector

$z$  = the susceptible human or human victim

$b$  = bionomics of man and the species of *Anopheles* in the area

$e$  = the influence of environmental factors

$p$  = *Plasmodium*, species and strains

$t$  = treatment and/or other attempts at control

$i$  = the level of immunity, racial or acquired

For a complete and detailed discussion of these various factors, the reader is referred to one of a number of monographs and books on malaria.

**BIONOMICS OF ANOPHELINES.** The bionomics of the mosquito vector continues to be the focal point in considering attempts at eradication or control of malaria. Each species of mosquito has fairly well defined food preferences, flight habits, and requirements for breeding and larval development. In some cases, forms which are closely related taxonomically, even different varieties of the same species, may differ in one or more of these characteristics. Thus, to fully appreciate the role of a given species or subspecies of anophelines in malaria transmission, and thus the best method of attack, one must know the biological requirements of that form. Probably most, if not all, of the approximately 200 species of *Anopheles* are susceptible to infection with human malaria and the gametocytes are capable of development within them when taken in with a blood meal. While all species of *Anopheles* appear to be susceptible to malaria they probably are not equally susceptible, and there is evidence that even within a species genetic strains of greater or lesser susceptibility may be developed. Nutrition may also influence susceptibility. Epidemiologically, however, these factors appear to be of minor importance in comparison with the question of whether or not they have the opportunity to feed on man, and avail themselves of that opportunity. This factor alone limits the dangerous malaria transmission to about two dozen species of *Anopheles*.

A number of anophelines which have been shown experimentally to be potential vectors appear to play no such role in nature because they prefer animal to human

blood. Thus anthropophilous anophelines, i.e., those which prefer human blood and under comparable conditions, much more effective vectors than zoophilous species. Since anophelines usually bite at night, the most efficient vectors are those anthropophilous species which come into human habitations, feed at night, rest in dark corners during the day and remain or return to transmit the infection from one member of a family to another and from one family to another. *A. darlingi* is one of the most domestic of all the anophelines and, because of this fact, can maintain endemic malaria at lower mosquito densities than most other species; certainly it is the best vector in the Western Hemisphere. An anopheline which feeds indifferently on man and animals may be an important vector when present in large numbers when animal food is not abundantly available or under other specialized circumstances. Even a zoophilous mosquito may transmit malaria when its abundance exceeds the opportunity for feeding upon animals. Malaria in central Europe at the turn of the century, and again after World War I, was apparently transmitted under such circumstances by the zoophilous *A. maculipennis*. Similarly, the transmission in the United States has been by *A. quadrimaculatus*, which may be classified as a zoophilous species or, at least, as an indifferent feeder on man. *A. pseudopunctipennis* which occurs in the Pacific areas of the Americas from the United States to Chile and the Argentine is zoophilous throughout most of its range and, thus, of little or no concern in the transmission of malaria, but in certain Andean valleys in South America and in part of Mexico, it more commonly frequents human habitations and, thus, is a malaria vector in those areas. A rather different situation is seen in north Holland where a normally zoophilous species (*A. atroparvus*), when trapped in the houses with the onset of cold weather, transmits malaria in the late autumn and early winter.

The normal flight range of mosquitoes from breeding sites in search of blood meals limits sharply the extent of the malaria around waters in which the larvae develop. Most of the *Anopheles* do not ordinarily fly much beyond a half mile or a mile from breeding habitats.

Each species of mosquito has its own preferred breeding sites, often very restricted, which, together with the limits of the flight range of that species, limits the area over which it transmits malaria. Until the advent of the attack on the adult mosquito, particularly with residual sprays, the bionomics of the aquatic stages was of primary concern to the malariologist in planning the antilarval measures. We are not yet prepared to totally disregard these aspects of malariology but it will be sufficient to indicate some of the different types of habitats in which the larval stages of various *Anopheles* develop. Most anopheline species, like *A. quadrimaculatus* in the United States, prefer sunlit or partially sunlit fresh waters, usually shallow pools or shallow margins of larger bodies of water. However, almost every type of water is used by one or another species, from large open brackish water or sea water lagoons (*A. sudaicus*), or densely shaded jungle morasses (*A. umbrosa*), to margins of foothill streams (*A. minimus*, *A. fluviatilis* and others), wells and cisterns (*A. stephensi*), and small collections of waters held by growing plants (*A. bellii* and *A. cruzi*). Others (such as *A. gambiae* and *A. albimanus*) utilize a wide variety of types of water, ranging from temporary rain waters, even those in hoof prints, to large bodies of water. Several species (including *A. albimanus*) are found in both fresh and brackish waters.

The distribution, habitat of the aquatic stages, food preferences of the adult female, and relationship to malaria of some of the more important vectors is summarized in Table 6-1. Many species not included in this table may be vectors of importance in local areas or may be vectors of secondary importance in highly endemic areas.

**THE BIONOMICS OF MAN.** The history of malaria is to a large extent the creation by man of conditions essential for the increase in the density of potentially dangerous anophelines. The history of attempts at control are replete with accounts of efforts to eliminate or obviate these man-made conditions. While this is hardly unique for malaria, it often is so clearly illustrated as to serve as an example of how man creates his own disease conditions. It is true, however, that naturally occurring factors in human biology, beyond the immediate control of man, may and do influence the epidemiology of malaria. The effect of race may be subtle but real. The Negro race is partially or completely refractory to most strains of *P. vivax*, usually suffering little from the infection and, in general, are not good carriers of gametocytes. On the contrary, since they suffer so little from the infection, some may become gametocyte carriers without ever being suspected of that role. Negroes may be even more potent carriers of gametocytes of *P. falciparum*. Age, perhaps, more than race, has its influence on the epidemiology of the disease. Evidence has been presented in a number of areas that children maintain a much higher gametocyte count for a much longer period after recovering from the clinical effects of the disease than do adults of any race (Swellengrebel and De Buck, 1938). There is no evidence that any intrinsic factor related to sex influences the course of malaria but in specialized circumstances habits and activities may bring one sex into greater contact with the mosquito vectors.

However, in general, man influences the course of malaria in a community in his normal activities by the manner in which these activities create or reduce mosquito densities, and afford opportunity for the mosquito to feed on man. Thus, in the colonization of the Western Hemisphere, the forests were cleared, thus exposing the margins of lakes and ponds to sunlight. Ponds were created by excavations and by damming streams, and even by partial filling and incomplete draining of swamp-lands for water supplies or water power. Incidental ponds were created in gravel pits, and borrow pits along highways and railways. The opportunities were thus multiplied many fold for the breeding of *A. quadrimaculatus* from the Atlantic Coast to the Rockies and for *A. freeborni* on the West Coast. To an appreciable degree the human habitations were built individually or in village or city groups around these impoundments. Accordingly, malaria followed the settlers across southern United States and northland on the East Coast to upper New York and New England, up the Mississippi Valley to North Central United States, and on the West Coast as far north as Oregon. Northern soldiers returning to their homes from the southern campaigns after 1865 contributed their supply of gametocytes to help reseed the northern areas.

With continued development of agriculture and increased use of land, without any attempts at specific control, malaria gradually receded to the more favorable southern climates. It is difficult to evaluate the role of any specific measure but it seems probable that continual clearing and draining with tilling of the soil eliminated many water collections, the increased amount of livestock diverted some of the

Table 6-1. Some of the more important anopheline vectors of malaria  
The most efficient vectors are marked with an asterisk (\*)

Species	Habitat of Aquatic Stages	Distribution and Relationship to Malaria
<i>A. quadrimaculatus</i>	Almost exclusively in sunlit or partially shaded permanent types of pools or margins of larger bodies of water such as ponds, lakes, or even slow moving rivers with a cover of vegetation or flotsam to protect them from predators. Acid waters, such as swamp waters, are unsuitable.	East coast of Mexico to New Hampshire, west through Ontario to Minnesota. A zoophilous species but, when abundant, transmits malaria effectively. The only significant vector in the eastern half of the United States.
<i>A. pseudopunctipennis</i>	In sunlit pools and in stream beds, especially those with surface mats of <i>Spirogyra</i> or other algae.	From southwestern United States to northern Chile and Argentina. A zoophilous species in most of its range but, when abundant, transmits malaria. A vector in parts of Mexico and in certain Andean valleys of South America.
* <i>A. darlingi</i>	In clear fresh shaded or partially shaded waters or lagoons, overflows, or marshes, often among matted vegetation.	Southern part of Mexico, Guatemala, Honduras and South America east of the Andes southward to Argentina. This is one of the most domestic and anthropophilous species, particularly in Brazil, Venezuela and the Guianas where it constitutes one of the world's most dangerous malaria vectors.
* <i>A. albimanus</i>	In a wide range of sunlit waters fresh, stagnant, or brackish; in temporary rain pools, ponds, margins of streams, and even among the floating mats in larger, deeper bodies of waters, such as lakes; it is even found in water troughs, cisterns or tanks.	From the Texas border south through Mexico, Central America, and the Caribbean Islands to Colombia and Ecuador, east to Venezuela. It is an avid feeder on both man and animals but while it freely enters houses it does not tarry there long. It is a dangerous vector in part of its range, particularly in Central America, east coast of Mexico and some of the West Indies.
<i>A. aquasalis</i>	In brackish tidal waters either sunlit or shaded. May breed in fresh water such as the rice fields of Trinidad.	Caribbean and Atlantic coasts from Costa Rica to the state of Rio Grande do Sul, Brazil, Trinidad and the Lesser Antilles. Apparently zoophilous and unimportant in much of its range but the principal vector in Granada and coastal Trinidad and of some importance in certain areas of coastal Brazil.
<i>A. bellator</i>	In water collections in arboreal epiphytes (bromeliads) in Trinidad, terrestrial bromeliads in Brazil.	Trinidad and southeastern Brazil. Wild mosquitoes, do not readily enter houses and rarely rest there but attack man viciously in the open. A vector in inland Trinidad and important in southern Brazil.

Table 6-1 (cont.). Some of the more important anopheline vectors of malaria

The most efficient vectors are marked with an asterisk (\*)

Species	Habitat of Aquatic Stages	Distribution and Relationship to Malaria
<i>cruzi</i>	In terrestrial and arboreal bromeliades.	Southern Brazil. Apparently also a wild species but the principal vector in part of its range.
<i>labranchiae</i>	Sunlit brackish coastal marshes and tide waters; inland in various sunlit waters, notably rice fields.	Southern Spain, western Italian littoral, Dalmatian coast, the western Mediterranean coast of Africa, and the highly malarious Mediterranean islands of Sardinia, Sicily, and Corsica. A domestic and anthropophilous species. A very important vector.
<i>l. atroparvus</i>	Prefers sunlit brackish waters but is found in fresh waters, notably the rice fields of Spain and Portugal.	From England across northern Europe to the Baltic, possible range and extension east of the Baltic not clearly established; extends south into Portugal and Spain. A zoophilous species throughout its range. Where abundant in Russia and the rice growing areas of Spain and Portugal, it is an important vector; transmits "winter malaria" in the Netherlands.
<i>A. sacharovi</i>	Sunlit brackish tidal waters or coastal marshes, also in sunlit fresh waters.	North and central Italy, the Balkans, Near East, central Russia east to West China. Feed indiscriminately on man and animals, readily enter houses. A known vector of importance in Italy, the Balkans, and Palestine.
<i>A. superpictus</i>	Associated with mountain or hill streams, in pools, receding streams, in irrigation ditches, and seepages; have even been taken from almost imperceptible water among rocks in receding streams.	Spain, Italy, the Balkans, southern Russia through Asia Minor to southwest India. Anthropophilous and readily enter houses. An important vector in some areas of the Balkans and Iran.
* <i>A. gambiae</i>	Sunlit fresh water both temporary and permanent rain, pools, pits, even hoof prints, ponds, roadside ditches, drains, irrigation furrows, margins of ponds or lakes and, on occasion, in floating mat of larger bodies of water.	Tropical Africa, Madagascar, and the Mascarenes, was introduced into and eradicated from northern Brazil. Anthropophilous but does not consistently go into dwellings, apparently does not tarry there long. A dangerous vector. It has been estimated that three quarters of all the malaria in Africa is transmitted by <i>A. gambiae</i> .
* <i>A. funestus</i>	In permanent streams, particularly backwashes, marshes and temporary pools in river beds.	In much of tropical Africa. An anthropophilous and very domestic species, a dangerous vector, particularly in East Africa from Ethiopia south to Rhodesia.

The most efficient vectors are marked with an asterisk (\*)

Species	Habitat of Aquatic Stages	Distribution and Relationship to Malaria
* <i>A. culicifacies</i>	Sunlit permanent or semipermanent collections of fresh water, irrigation channels, borrow pits, rice fields, and occasionally in brackish water.	Primarily in the plains but extends into the foothills of India, Burma, Ceylon, Thailand and Yunnan Province of China; has been reported from Arabia. A zoophilous species but will feed readily on man in houses, rests in houses or cattle sheds. A weak vector but because of density is one of the world's most important vectors. The principal vector in India, the only known in Ceylon; vector in parts of Burma.
* <i>A. fluviatilis</i>	Sunlit margins of foothill streams, stream pools, and irrigations, sometimes on margins of standing water, viz., lakes, tanks, etc. Rarely below 1,000 ft. elevation; extends to 5,000 ft.; has even been found above 7,000 ft.	Primarily in the Indian area from Baluchistan to Burma; reported also in Turkestan, Thailand, and Tonkin. Apparently an anthropophilous and domestic species but readily feeds on cattle also.
* <i>A. minimus</i>	In grassy margins of slow-moving sunlit streams up to 2,000 ft. elevation; in Shillong up to 5,000 ft. in backwashes and overflow during monsoon, in pools and eddies of larger receding streams during dry season. Can utilize rice fields on occasion.	India (eastern and northern), Ceylon, Burma, Assam, Thailand, Indochina, southern China, and Formosa. Anthropophilous in most of its range and readily enters dwellings. A dangerous vector throughout its range but particularly in the foothills of north India, Burma, and southern China, Assam.
* <i>A. minimus flavirostris</i>	Shaded marginal pools, and eddies of slow-moving foothill streams up to 1,500 to 2,000 ft. elevation; also edges of irrigation ditches, canals and rivers. Never in salt water or in such waters as those in rice fields.	Foothills of the Philippines, Celebes and Java. A wild mosquito which feeds indiscriminately on small animals; will enter dwellings to feed but does not rest there. The only vector in the Philippines but a dangerous one there.
* <i>A. sundaicus</i>	Sunlit brackish or salt water lagoons, swamps or ponds protected by coastal embankments.	India, Burma, Thailand, Malaya, Indochina, Sumatra and Java (Celebes and Borneo). A very strong flier, up to three miles, anthropophilous but will feed readily on animals as well, found in large numbers in human dwellings and cattle sheds. Principal vector in coastal Bengal, Malaya, Indochina, Sumatra and Java.

Table 6-1 (cont.). Some of the more important anopheline vectors of malaria

The most efficient vectors are marked with an asterisk (\*)

Species	Habitat of Aquatic Stages	Distribution and Relationship to Malaria
<i>A. maculatus</i>	Sunlit hill streams and springs feeding such streams up to 4,000 ft. elevation; also found in rice paddies, pools and other standing waters.	Foothills of Asiatic mainland from India to south China and in Formosa, the Philippines and Dutch East Indies. Appears to be zoophilous and thus relatively unimportant in most of its range. Anthropophilous in Malaya, enters houses freely but does not tarry there. The most dangerous vector in the Malayan foothills.
<i>A. umbrosus</i>	In deeply shaded stagnant pools and morasses in the jungle, in deeply shaded brackish waters in the mangrove swamps. Encountered on occasion in more open waters with less intense shade.	Tonkin, Cochin-China, Malaya and Dutch East Indies. A wild species, adults are strong fliers, fierce biters, and usually found in the deep jungle. Apparently zoophilous but readily bites man and will enter dwellings to feed. An important vector when abundant, viz., Malaya.
<i>A. hyrcanus</i> , <i>sinensis</i>	Sunlit quiet waters, such as rice fields, ponds, lakes, swamps, impounded waters, slow streams and stagnant waters, such as canals.	Northeast India, Burma, Indochina, China, Korea, Formosa, and Japan. Apparently readily bites both man and animals, enters dwellings freely and remains there. The most important vector in lowland China and extends into the hills, apparently the only vector in Yangtze Valley of China and in southern Japan.
<i>A. punctulatus</i> complex ( <i>P.p. punctulatus</i> , <i>P.p. farauti</i> )	Sunlit shallow waters, prefer muddy waters such as temporary rain pools, waters in new depressions and excavations either small or fairly large, found nearly as plentiful in fairly clear permanent waters such as stream margins. Found also in brackish water, even in the bilge of small boats. Most abundant near settlements.	Australasian region, viz., Northern Australia, New Guinea, Solomons, New Hebrides and adjacent islands. Feed readily on both man and domesticated animals, enter dwellings to feed but usually do not remain, rest mainly in the dense underbrush. Dangerous vectors throughout their range, particularly when dense.
<i>A. leucosphyrus</i>	In bottom of densely shaded pools, beds of shallow streams, jungle seepages.	India to Malaya, Dutch East Indies. A wild species, but enters houses well after midnight and leaves immediately after feeding. The only vector in Borneo but dangerous there. May be more important than is realized in other areas.

*A. quadrimaculatus* from man, and the development of screening against insect pests in general, appear to have interrupted transmission in the marginal northern communities. Hackett stresses this same sequence of events, with particular stress on the diverting role of increased livestock in the progressive reduction to the point of its elimination in Central Europe by the beginning of World War I, its resurgence with the disrupted economy and reseeded by malaria-carrying veterans, and disappearance again between World War I and World War II; in this area the zoophilic species, *A. maculipennis*, population did not change as much as the domesticated animal population. The mosquitoes were overabundant or not, only in relation to the availability of domesticated animal sources of food. Similarly, it was the subtle influence of human activities, rather than specific control measures, which appeared to have reduced malaria in the marginal areas of Italy and led the Italian malariaologists to speak of "bonification." In Trinidad, the planting of the immortal tree to provide shade for the cocoa trees also provided ideal hosts for the parasite epiphytes, bromeliads, in which *A. bellator* breed, and thus a local malaria problem was created out of growing cocoa. The flooding of lands for rice cultivation has provided excellent and abundant sources of *A. labranchiae* in Portugal, *A. culicifacies* in India, and *A. hyanais sinensis* in China and created malaria problems in those areas. The development of commercial fish culture in Java provided an abundant source of *A. sundaiensis* in the brackish waters of these ponds.

Military operations have not only encountered serious malaria problems but have not infrequently intensified or even created the problem. Thus, troops at advance positions are without benefit of protective netting or screening at night and become the victims of malaria. It was particularly observed in the South Pacific campaigns of World War II that artillery barrage, bombings and, to an even greater extent, the construction of airstrips, roads, and semipermanent quarters, create ideal breeding places in close proximity to troop concentrations. Thus, *A. punctulatus farauti* commonly multiplied many fold over their normal density and were often concentrated close to permanent or semipermanent installations. In some cases such mechanized clearings opened the way for the even more effective vector *A. punctulatus punctulatus* and the malaria problem was created by the necessities of military operations. Even in an attempt to escape malaria the lack of precise information may actually create the problem. Thus, following the Spanish-American War, when the only known vectors of malaria were quiet water breeders, the barracks for troops were built up in the hills away from the "marshlands" and thus in the only malarious part of the islands, since the only vector there is the stream breeding *A. minimus*.

It is not to be assumed that the malaria-carrying mosquitoes and the transmission of the disease is wholly dependent on the organized efforts of man in the support. Malaria exists in tropical Africa and among other native populations where the living requirements are primitive and where man has altered the environment very little. Nevertheless, even in such areas, the direct support of malaria and the intensification of the problem through increasing the density of mosquitoes is much more common than is indicated even by the few examples cited.

**INOCULATION MALARIA.** Although malaria is normally transmitted from man to man by anopheline mosquitoes, it may be transmitted directly by blood inoculation. Thus, malaria has been accidentally transmitted by transfusion with blood from

infected donor (Wright, 1938). Since the favorable reports by von Jauregg in 1922, malaria has been induced by blood inoculation in the treatment of paretics. Experimentally infected mosquitoes from laboratory colonies have also been used to transmit malaria to paretics. However, neither the accidental transmission of malaria in transfusion, or its intentional transmission to paretics, has resulted in any demonstrated outbreak of secondary cases of malaria.

However, extensive outbreaks of severe *P. falciparum* malaria have occurred in both New York City and Cairo, Egypt, from accidental transmission among drug addicts by the use of unclean hypodermic syringes (Most, 1940). Probably other similar, but unreported, outbreaks have occurred.

ENVIRONMENT. From this discussion are excluded those environmental factors which are influenced directly by man, which have been discussed above, but those naturally occurring phenomena which are beyond the control of man are considered.

Climatic factors, particularly temperature, have a marked limiting effect upon the distribution of malaria. While seasonal fluctuations may and do influence the distribution of the several species of malarial parasites, it is the effect of low, or even high, temperatures upon the sporogonous cycle of the malaria parasite within the mosquito which results in limiting the distribution. Many anophelines will survive and thrive at temperatures which will not support growth of the parasite in the mosquito. Stratman-Thomas, in 1940, found that *P. vivax* did not develop in *A. quadrimaculatus* at temperatures below 15° C (59° F) and required 38 days to complete development at this temperature, whereas they complete development in eight days at 30° C (86° F), the maximum temperature at which they would develop. Furthermore, exposure of the mosquito for more than a few days to temperatures less than 10° C (50° F) or more than 18 to 24 hours at 37° C (98° F) prevent subsequent development of the parasites. The temperature alone would limit transmission in temperate zones to the summer season and reduce the amount of that transmission during midsummer. Siddon (1944), working with *A. culicifacies* in India, found that while *P. vivax* would develop at 10° C (50° F), the development of *P. falciparum* only rarely occurred and *P. malariae* never developed at this temperature. Thus, the temperature requirements for the sporogonous cycle in the mosquito alone would sharply limit the geographical distribution of the latter two species.

Most species of mosquitoes require a relatively high atmospheric humidity for survival and development but there is evidence that the parasitized mosquitoes are even less resistant to the drier airs and that the parasites within them have a higher requirement of atmospheric moisture than do the mosquitoes themselves.

BIONOMICS OF THE PARASITE. In addition to the fact that the malaria parasites require mosquitoes for their transmission from man to man and are dependent upon favorable atmospheric conditions for their incubation within the mosquito, there are certain intrinsic factors which, in part at least, govern the biological potential of the several species and strains. To an appreciable degree the process of natural selection has fitted the several strains with the different ecological environments.

Typically (i.e., most of the known strains), *P. vivax* malaria develops a parasitemia with resulting clinical manifestations, during the second or third week after infection from the mosquito bite. Relapses occur within a year but the disease be-

comes quiescent within two to three years. The St. Elizabeth strain has been shown by Coatney and his co-workers to typically relapse 9 to 12 months after the primary attack and this is the pattern usually associated with the overwintering in the subsequent spring relapse of *vivax* malaria in the temperate zone. In the tropics where more or less continuous transmission occurs, both strains with this delayed relapse pattern and those without this delay have survived. Thus, the Madagascar strain characteristically relapses six months or more after the primary attack whereas the Chesson strain (South Pacific) and the McCoy strain (Florida, U.S.A.) more frequently relapse one to three months after the primary attack. Perhaps the best known example of natural selection of strain for a particular ecological environment is that which has occurred in the Netherlands. The strain of *P. vivax* which has persisted is transmitted largely by zoophilous mosquitoes trapped in houses in the fall and has a long incubation period (three to nine months). Thus, the primary parasitemia and primary clinical attack comes the following summer or fall, with continued supply of gametocytes for the mosquitoes remaining in the houses during the second fall and winter. This strain is not prone to relapse.

*P. falciparum* malaria, while a much more fulminating type of disease, usually does not relapse clinically but may relapse parasitologically. However, parasite production in relapse is usually of a low order and of short duration so that it is well adapted for survival in areas with long periods without mosquitoes. Thus, it is basically a tropical infection and less well adapted than *P. vivax* for survival in the temperate zone.

Although *P. malariae* is a highly relapsing species, the total parasite production is low and it requires a much longer time than the other species for development in the mosquito; hence it is a much less ubiquitous species.

*P. ovale* is found commonly only in parts of tropical Africa, although it has been reported elsewhere in the tropics. It is characterized by low parasite production, short period of parasitemia even in the primary attack, and failure to relapse. Thus, it is able to survive only where the optimum conditions for transmission occur.

**Treatment and Control.** There is no evidence that mass treatment has ever eradicated or done more than temporarily suppress attack rates in the treated population. On the contrary, it cannot be asserted that treatment has no influence on the transmission rate in a community. Since the therapeutic agents which have been and are still in use (quinine, quinaquine or atabrine, chloroquine, and paludrine or chlo-guanide) both in individual and mass therapy are not primary gametocidal agents but attack primarily the erythrocytic schizogonous cycle, their obvious effect is to prevent or cure disease by the destruction of these stages in the blood. The sustained use of such drugs as chloroquine or quinaquine (atabrine) for a long period (i.e. year) in the permanent populations in the tropics, or throughout the entire transmission season in the temperate zones, probably reduces transmission during the period of therapy if a significant fraction of the population partakes of the therapy. However, the possibility that gametocytes may be derived, in part at least, from underlying exoerythrocytic schizogony rather than from the erythrocytic schizogony (Lewert, 1950) should not be completely overlooked in considering the role of sustained therapy in the transmission of malaria. Where therapy is systematically administered for a shorter period to those with overt malaria, or even when those with prodromal signs are included, it is questionable whether there are any sig-

ant reductions in the total community supply of gametocytes. The possible effect of the annual consumption of chill tonics containing quinine in home medication in the southern United States before World War II is even more subtle. The hope held in some quarters, perhaps more in desperation than faith, that therapy would prove to be of significant value in the community control of malaria transmission appears to have been abandoned. Nevertheless, continued use of therapeutic agents may have played a role, hardly discernible among the other factors in the epidemiology of the disease in such marginal areas as the southern United States. The role of therapeutic agents in preventing overt malaria will be discussed under control.

In addition to community-wide organized procedures for the prevention and control of malaria, more subtle efforts in community and individual activities have had significant effects. Mention has already been made of bonification, i.e., continued draining for agricultural purposes, the increased raising of cattle in the United States and Europe, and improved housing. To these may be added the increased use of various insecticides by individual householders. Anyone who has worked in the rural areas of the southern United States will be impressed with the amount of such sprays which has been used in the past two decades. With the advent of DDT, the effectiveness of such household spraying must have increased. However, the use of pyrethrum sprays, and even less effective sprays, must have had a significant effect upon malaria transmission. Probably in no other country has spraying by the individual householder been as common a practice as in the United States. It seems likely, also, that such individual efforts would have their greatest effect in an area such as the United States, where transmission by a zoophilous mosquito makes the disease vulnerable to attack.

**Immunity.** Malaria does not elicit a protective immunity comparable to that of smallpox. Thus it has been easy to overlook the probability that immunity plays a powerful role in maintaining various degrees of health in a highly malarious region. In considering immunity, stress may be placed on specific acquired immunity which may or may not play a part in so-called natural immunity and, finally, consideration should be given to the interference of malnutrition upon the development or effectiveness of immunity.

The fact that Negroes are usually quite resistant to *P. vivax* and often suffer less from *P. falciparum* than do whites is commonly ascribed to a natural or nonspecific immunity. There is some evidence in Africa and in Panama that Negro children are susceptible to malaria and that only with continued exposure as they grow older do they develop the protective immunity associated with race. Nevertheless, it is true that adult Negroes with no known previous infection may not develop an overt malaria or even parasitemia upon inoculation with *P. vivax*. However, as Huff points out, there is no indication as to whether or not pre-erythrocytic malaria developed from the inoculum or from previous unknown exposures. Furthermore, Butler and Saper (1947) found that Negro troops exposed to new strains of *P. vivax* in the Pacific area were just as susceptible to infection as whites. It is evident that acquired immunity is at least a factor in the resistance of Negroes to malaria. The recent suggestion that the sickling trait is associated with marked resistance to malaria needs further study.

Most of the critical studies on specific acquired immunity have been conducted with avian and simian malaria. Many of the earlier studies utilized blood inoculations rather than the normal sporozoite infection; this may account for the fact that

the results have often been inconclusive or ambiguous. It is clear, however, that some degree of immunity may persist for months and even years after the last evidence of infection. Thus, in a highly endemic area repeated exposure to infection would provide the stimulus for the maintenance of a highly protective immunity. In tropical Africa such protection of the adult native population has been purchased at the cost of a high infantile morbidity and mortality rate. It has been suggested that any attempt at malaria control, unless it can be developed quickly into complete eradication, might merely increase the amount of malaria in the community by reducing the immunity which is maintained. The argument is not without merit but appears to disregard the fact that such immunity is bought at the price of a high infant morbidity and mortality rate.

In both avian and simian malaria, the serum of the immune animal has both agglutinating and lethal antibodies. Phagocytic cells complete the destruction of the parasites. Thus, the pattern is in keeping with the usual concepts of immunity. However, such immunity is not sufficient to completely overwhelm a new infection except when it is at or near its maximum level; repeated stimuli are apparently necessary to maintain high protection. Furthermore, the immunity is not only largely species specific but, to an appreciable degree, strain specific within a species. Yet even this apparent specificity may be merely quantitative. Boyd and Kitchen have shown that patients recovered from *P. falciparum* infection are partially refractive to new strains of that species. They become infected but suffer comparatively little of the usual pathology. Furthermore, in patients simultaneously inoculated with *P. falciparum* and *P. vivax*, the former will develop and the latter be completely suppressed for some time. Months after recovery from *P. falciparum* malaria, the patient may "relapse" with *P. vivax* malaria. This sequence of events was encountered in military personnel who were unprotected in highly malarious combat areas.

The immunity then is of a comparatively low order and offers complete protection only at its maximum level. Any interference with its development or maintenance will diminish the degree of protection. Apparently, malnutrition is one of the factors which interferes. Relatively little experimental work has been done on the few studies which have been conducted are in accord with similar studies on other parasites (e.g., hookworms and *E. histolytica*) the immunity to which appears to be barely protective. By way of example, Brooke (1945), working with *P. relictum* in pigeons found that a thiamine deficiency interfered with the normal development of immunity to this malarial parasite.

**Malaria Prevention.** Malaria prevention may be conveniently contrasted with control or eradication. Under the heading of prevention may be included such measures as the use of repellents, drug prophylaxis, and the screening of houses. Such measures may be considered as defensive, in an attempt to protect the individual or a selected portion of the population. These may be combined with offensive measures of attack and have their value even today.

Mosquito repellents have their uses among combat troops, hunters, or others who must be abroad at night in malarious areas. Such repellents, however, effective under laboratory conditions, have never been adequately evaluated as the means of preventing malaria in the field. Their use is considered largely in the nature of an emergency measure. They are discussed more fully in Chapter 7.

**Drug Prophylaxis.** None of the therapeutic agents available for routine administration is capable of preventing infection with *P. vivax* and only one of the available drugs is believed to have such effect upon *P. falciparum*. Thus, causal prophylaxis, or true *prophylaxis* is not obtainable against *P. vivax*. However, a number of compounds, quinacrine and the 4-aminoquinolines, will destroy the erythrocytic schizogony as it develops and thus effect *clinical prophylaxis* or suppressive treatment of both *P. falciparum* and *P. vivax*; fewer critical tests have been conducted with *P. malariae* but so far there has been no clear-cut difference between the results with this species and the two more common species. Thus, with all of these drugs, there is little or no interference with the underlying exoerythrocytic schizogony but rather the recurring crops of erythrocytic stages are destroyed in the circulation before overt malaria, or even readily demonstrable parasitemia, can develop. With *P. falciparum* the continuation of the drug prophylaxis for a comparatively short time after known exposure will usually completely prevent the development of malaria. Apparently as little as 10 days' continuance of drugs beyond exposure may suffice to completely prevent the development of *falciparum* malaria but it is generally conceded that a month's treatment beyond exposure will give almost complete assurance of preventing *P. falciparum*. Thus, although technically these drugs are not causal prophylactics, for all practical purposes they serve this purpose in *falciparum* malaria. Therefore, the demonstration that chloroguanide (paludrine) is a true causal prophylactic for *falciparum* malaria does not recommend it above quinacrine or the 4-aminoquinolines.

The results of chemical prophylaxis against *P. vivax* is, however, quite different from that against *P. falciparum*. With the use of chloroguanide as well as with the use of quinacrine and the 4-aminoquinolines overt malaria develops after the termination of the drug prophylaxis. It is postulated that the exoerythrocytic schizogony continues much longer with *P. vivax* than with *P. falciparum* and thus provides the source of the parasitemia. While it is not impossible that the time in which malaria develops after the termination of drug prophylaxis may bear some relationship to the particular drug used, the most conspicuous relationship seems to be to the strain of *P. vivax* involved and the duration of the postexposure treatment. There is even some suggestion that the continuation of drug prophylaxis for 18 months beyond exposure may entirely prevent the development of *vivax* malaria. This is in accord with the evidence that *vivax* malaria frequently runs its full course in less than two years. On a practical basis, however, it may be preferable to continue drug prophylaxis only a month after exposure and thereafter treat those cases which develop rather than attempt the sustained therapy for 18 months or more.

Usually, drug prophylaxis is desired for relatively short periods of exposure but on occasion the procedure may be necessary or desirable for much longer periods. Experience in World War II has shown that quinacrine (atabrine) may be taken effectively and safely for a full year during exposure to infection and reinfection. Clark has recently found that chloroquine and chloroguanide may be taken effectively for a year. Boldt and Goodwine (1949) have continued chloroquine for two years without outward effects and with continued effectiveness. Thus, these compounds offer promise of suppressing malaria where unprotected exposure is required for short, or even protracted periods. However, there is no clear demonstration that the community level of infection can be more than temporarily

depressed. The hope that such drugs could be used to eradicate malaria in a community is still without demonstrated support.

The same drugs which are effective in clinical prophylaxis are also the most satisfactory in effecting clinical cure since in both actions the attack is upon the same stage of the parasite. Since *falciparum* malaria does not commonly relapse, treatment of this infection is for all practical purposes usually curative. However, with *P. vivax* infection relapses occur largely in accordance with the pattern of the particular strain. Relapses should be treated in the same manner as the primary attack.

Since quinacrine, the 4-aminoquinolines, or chloroguanide do not serve either for *causal prophylaxis* or *complete cure* attention has been given to other types of compounds. Attention has been given to the 8-amino quinolines. Of these, primaquine has already proved useful in eliminating *vivax* malaria from United Nations troops returning from Korea. It is not without danger of toxicity, particularly to Negroes. However, it was safely and effectively used in over 300,000 personnel doses of 26.5 mg. primaquine diphosphate (15 mg. base) daily for 14 days (Archambeault, 1954).

The uses and limitations of these several drugs have been reviewed by Coggeshall and Craige, Saper, and Dove in Boyd's *Malariology* (1949) and by Coatney and others (1950a, b), Cooper and others (1950) and Lints and others (1950). Amodiaquin (camoquin) and pyrimethane (daraprim) have been introduced more recently. The latter is markedly gametocidal but is not recommended for continuous suppression of malaria. However, four drugs may be considered for the suppression of malaria. They should be taken throughout the period of exposure and for one month thereafter:

1. Quinacrine (atabrine): 0.1 gm. daily or at least six days a week.
2. Chloroquine (aralen): 0.3 gm. once a week (once every seven days).
3. Amodiaquin (camoquin): 0.3 gm. once a week (once every seven days).
4. Chloroguanide (paludrin): 0.3 gm. once a week (once every seven days).

**Screening of Houses and Use of Bed Nets.** The use of protective screening both the use of bed nets and the screening of living and sleeping quarters, offers effective protection to those who use them nightly. The demonstrations of the effectiveness of screening in preventing malaria in such protected individuals has been so frequently and clearly demonstrated that detailed discussion is unnecessary. It is probable that the increase in the number of screened houses, not necessarily a malaria control measure, in the United States has been a factor in the reduction of malaria in the marginal areas of this country. Many houses in the United States are difficult to screen and it is even more difficult to maintain such screening. In highly malarious areas of the tropics screening of the native dwellings would be almost impossible even if sufficient funds were available. Thus, screening can hardly be considered as a practical measure in any attempt to eradicate or even control malaria on a community wide basis in such areas.

**Control and or Eradication of Malaria.** During the past decade there has been a marked tendency to change our focus of attack upon malaria from *control* to *eradication*. The impetus for this changing objective was the singular success in eliminating from northern Brazil, the potent malaria vector, *Anopheles gambiae*, which had invaded that country from Africa. The rapid recession, under con-

attack, of malaria from the United States and the demonstrated power of DDT in tropical America had added considerable hope that eradication from larger areas is technically possible in the near future. The principal mode of attack at the present time is through the use of residual sprays in homes and gathering places on an organized community basis. That this will suffice in all areas is not evident and certain doubts may be raised. Nevertheless, it is this approach which deserves major emphasis at the present time. It is the only technic which promises widespread control. This is a localized attack upon the mosquitoes which transmit malaria within houses. In most areas of the world this is so nearly the exclusive means of transmission, that what little transmission takes place elsewhere may be disregarded or relegated to the place of a minor secondary problem.

**Residual Spraying.** The attack upon the mosquito in the house was first considered a significant point in control by Prince. Both spraying and swatting the individual mosquito was utilized. This same approach was urged by Swellengrebel in attacking the problem in Holland. With the development of effective space sprays, the attack continued. Park-Ross first demonstrated the value of weekly spraying of the huts with pyrethrum as a malaria control measure in rural India. Russell and Knipe followed this with a more thoroughly controlled study and showed that the weekly spraying of houses during the transmission season, July through December, resulted in almost a 75 per cent reduction in detectable parasitemia of children and nearly a 50 per cent reduction in palpable spleens. However, there was no reduction in the mosquito (*Anopheles culicifacies*) population. The development of the use of DDT as a residual spray opened the way for the more effective attack on that *Anopheles* which came to the houses. Trapido (1946) showed that the application of DDT at roughly four-month intervals to the dwellings in a Panamanian village reduced the malaria rate more than 75 per cent in 14 months. The mosquitoes, *A. albimanus*, were markedly reduced in the houses. Immediately after the first, second, and third applications of spray, 2, 4, and 0 mosquitoes were taken as compared to 87, 40, and 88 in the control villages. Furthermore, there was much less tendency for these mosquitoes to feed; within a four-month period after the application of the spray, 0 to 17 per cent were engorged as compared to 27 to 74 per cent engorgement in the control villages. Thus, malaria transmission was promptly interrupted so that it is likely that some of the parasitemias discovered after 14 months may represent either relapses or infections contracted elsewhere. Furthermore, only 0 to 8 per cent of mosquitoes captured in sprayed dwellings survived for 21 hours as compared with 25 to 50 per cent survival of those captured in unsprayed dwellings. The effect upon the total population of *A. albimanus* was, however, much less impressive. Immediately after spraying there was a reduction in the catches in stables within the village but a gradual recovery in three to six weeks. As little as 300 feet from the village the effect was even less. Thus, while DDT residual prevents malaria transmission there is no evidence that it will eradicate *A. albimanus* and it is questionable whether its continued use for years would see a significantly sustained reduction in their number.

Similarly, Downs and others (1950) have shown that residual spraying in the rice growing towns of Morelos, in Mexico, has all but eliminated *P. falciparum* in five years and has brought the total malaria rate down to barely detectable levels and the vector, *A. pseudopunctipennis*, is rarely found in houses. While there ap-

pears to be some reduction in this mosquito in the immediate village, it is still very prevalent in the area. The mosquito has not been eradicated and some transmission of malaria takes place.

However, the use of residual DDT against *A. darlingi* in British Guiana and in Venezuela has apparently resulted in the elimination of the species in the area treated. Not only was malaria transmission reduced but within two years there was a diminution in both adults and larvae of *A. darlingi*. At the initiation of the work it was planned to apply residual DDT every eight months but by 1948 the interval was lengthened to 10 and 12 months. At latest report, five years after the initiation of the program, no *A. darlingi* larvae or adults can be found within the area covered by residual spray. It is visualized that application of DDT once every 12 months will be sufficient to prevent the resurgence of the mosquito population either from undiscovered foci within the area or infiltration from the periphery.

Similar results are reported by Gabaldon from Venezuela with the same vector.

A totally different picture is given by Smith and Dy (1949) in their attempt to control malaria transmitted by *A. minimus flavirostris* in the Philippines. The application of a residual of DDT every three months produced no discernible reduction in either malaria rates or the density of the mosquito vector. These workers note that this species is a "wild mosquito" and does not deliberately go to human dwellings to feed.

Thus, the effectiveness of residual sprays varies with the habits of the mosquito. Complete eradication of malaria and its vector appears possible by this means alone where transmission is by a highly domestic or anthropophilous species, such as *A. darlingi* of the northern coast of South America, but apparently it offers little or no opportunity to control malaria carried by a wild mosquito such as *A. minimus flavirostris*. It is possible that *A. bellator* of Trinidad and *A. cruzi* of southern Brazil, both "wild species," may not be completely prevented from transmitting malaria by residual sprays alone. Between the two extremes there appear to be ample opportunities for controlling malaria, even eradicating the disease, without actually eliminating the vector. In addition to the examples cited of this type of control in Panama and Mexico, there are reports of similar experiences in India. Singh and Singh (1949), Viswanathan and Rao (1949), and others have reported gratifying reductions in malaria rates following the use of residual sprays of DDT or gammexane (benzene hexachloride) due to the reduction of *A. culicifacies* and *A. fluviatilis* in the dwelling and other sprayed shelters. There is some reason to believe that continuation and extension of the control program may eliminate or markedly reduce the total population of the more domestic *A. fluviatilis* from large areas but there is less hope of so eliminating or reducing *A. culicifacies*. In the United States, the use of residual sprays has undoubtedly added its weight in the final elimination of malaria from this country without materially reducing the vector *A. quadrimaculatus*. The use of residual sprays has resulted in almost complete elimination of malaria from Italy, apparently with significant reduction in anopheline population. It should prove to be a particularly effective weapon against the wild transmitted malaria of Holland.

In Africa, the picture is less clear. There are reports of significant reduction in malaria transmission with or without anopheline reduction (Davidson, 1950). There are other reports indicating the failure of DDT to control either malaria

mosquitoes. *A. gambiae* appears to be the principal focus of uncertainty. Explanations of failures include the suggestion that this species is repelled rather than killed by DDT in low concentration, without interfering with feeding; that transmission takes place outside of the huts as often as within them; and that it is difficult to maintain adequate residual on mud huts. In some cases the possible failure of spray crews to follow directions has been suggested.

Thus, residual spraying offers the single most effective weapon known. In addition to DDT other residuals have been developed; these include benzene hexachloride (Bertram, 1950), lindane, chlordane, and others (see Chapter 7). To an appreciable degree at least it may be anticipated that the improved use of one or another of the residuals may permit more effective attack in such areas as Africa. However, the inevitable conclusion is reached that residual spray alone is not at present the total or final answer to the eradication or even the control of malaria in all areas. Some concern is felt over the possibility that DDT-resistant strains of anophelines may develop to complicate the program, since both flies and culicine mosquitoes have developed such strains in both the laboratory and in nature. Fortunately, so far no such strains of anophelines have developed and their greater susceptibility to DDT lends substance to the hope that such strains will not develop, at least not before malaria transmission has been reduced to the point where other techniques may be effective. Although residual spraying is classified as an attack measure leading to control or even eradication, there is so far no indication that the time may be anticipated even in the United States, British Guiana, or Venezuela, when the control measures can be completely terminated. The wave of malaria a quarter of a century ago in Bombay that resulted from the termination of control measures after the eradication of malaria (Covell, 1928) \* dictates that at least reconnaissance should be maintained.

**LARVAL DESTRUCTION.** When mosquito breeding is in limited, well-defined areas, the drainage of such waters or their control to reduce breeding still is an important part of malaria control. Water fluctuation control in such areas as the C.V.A. reservoir should be considered whenever possible in new impoundments in malarious, or potentially malarious, areas. Water fluctuations in rice cultivation are still effectively utilized in Europe and Asia. Malarial intelligence should be utilized in the clearing of jungles, in the impoundment of waters, and the creation of new concentrations of surface water. The use of larvicides, DDT or others, will still be needed. Larval destruction had largely eliminated malaria from northern Chile before the advent of residual spraying. Similarly, biological adjustment of the brackish water ponds of Java reduced mosquito breeding and eliminated malaria. Larviciding had an important part in eliminating *A. gambiae* from Brazil.

Destruction of the breeding places or the use of larviciding chemicals in the control of malaria transmitted by such wild mosquitoes as *A. bellator*, *A. cruzi*, and *A. minimus flavirostris* is still a possible problem. It may well be necessary to combine such measures with residual spraying in the control of malaria by such means, for example, as *A. albimanus* in Panama and *A. culicifacies* in India. In the attempt to completely eradicate malaria from the island of Sardinia, both larvicides and residual spray has been used against *A. labranchiae*. The cost so far is estimated at not less than \$12,000,000, and it is not yet certain that the goal has been

\* See Covell, in Boyd (1950).

accomplished (Logan, 1950).

CONCLUDING COMMENT. Hundreds of millions of people still suffer from uncontrolled malaria; it still remains one of the major diseases. Technics and weapons for control and eradication in large areas are available. They have been effectively applied in many localities. To what extent they can be adapted to use, and how effective they will be under the varying circumstances, is yet to be ascertained.

Malaria control has become very largely a socio-economic problem.

## YELLOW FEVER

LLOYD E. ROZEBOOM, Sc.D.

Yellow fever is an acute febrile disease characterized by jaundice, albuminuria and a tendency to hemorrhages, especially from the stomach (black vomit). It is due to a filtrable virus, and is spread by mosquitoes. All ages and sexes are susceptible. One attack produces a lifelong immunity. Negroes are as susceptible as whites, although the disease in them is milder and rarely fatal. There are few sequelae. The case fatality rate is ordinarily about 6 per cent, but occasionally it may rise to 60 per cent or higher in closed epidemics. The incubation period is usually two to five days, maximum six days.

The distribution of the disease is shown in Figures 6-1 and 6-2. It is present throughout the great forested areas of South America and Panama, and in a broad belt from 15° N. and 10° S. latitude in Africa. Extensions sometimes occur; between 1950-54 it spread to Trinidad and Central America as far as Northern Honduras.

Transmission by *Aedes aegypti*. The transmission of yellow fever through *Aedes* (*Stegomyia*) *aegypti* was proved by Walter Reed and the U. S. Army's Yellow Fever Commission. It was also shown that the virus was in the circulating blood of the patient only during the first few days of the disease, and that the mosquito which had ingested the virus was not able to transmit it by the bite until

**Fig. 6-1. Distribution of yellow fever in the Western Hemisphere.**

----- BOUNDARY OF YELLOW FEVER ENDEMIC AREA

Fig. 6-2. Distribution of yellow fever in Africa.

Map showing localities in which yellow fever cases occurred from 1921 to 1950. (Prepared by Dr. Henry Kumm.)

After 10 days or more. This is known as the extrinsic incubation period. Once infected, the mosquito remains so for the rest of her life. At first it was thought that man was the only vertebrate host, and that the epidemiologic cycle involved only man and *Aedes aegypti*. Since the patient could infect the mosquito only during a very short period of the active disease, and there were no reservoirs of the virus, it appeared evident that the disease could exist only in localities where there were always active yellow fever cases among nonimmunes supplied by immigration and births, and where *A. aegypti* could exist in large enough numbers to insure contact with the sick. Such conditions were met with only in large centers of population in the tropics, but during the summer months they were also present

in the cities in North America. *A. aegypti* was carried by sailing vessels and after escaping into northern port cities from these vessels, in a short time would build up dense populations during favorable weather. This mosquito is highly domestic and breeds in artificial water containers such as water barrels, clay pots, etc., in which there was an abundance before the installation of modern water and sewerage systems. The disease was introduced by active cases or by infected mosquitoes, and outbreaks occurred as far north as Philadelphia and New York.

The demonstration in Havana and Panama by Gorgas that yellow fever could be eradicated through control of *A. aegypti* was followed by extensive control campaigns in tropical cities, which were considered to be the endemic foci. This resulted in a steady decline of the disease and led to the hope that soon it would be eradicated from the entire world. But newer laboratory techniques, making possible surveys of immunity through the mouse protection test, and the viscerotomy series, which showed the presence of fatal cases through examination of the pathological picture in the liver, revealed the existence of extensive areas of rural endemicity not affected by the control of *A. aegypti*.

**Jungle Yellow Fever in South America.** Soper and his associates (1933) reported the occurrence of rural yellow fever in an area in Brazil where *A. aegypti* was evidently not the vector. Immunity surveys showed that the tree-dwelling monkeys are susceptible to the virus, and captures of wild mosquitoes followed their inoculation into susceptible animals has resulted in the isolation of the virus from several species of forest-dwelling mosquitoes. Laboratory studies proved that a number of mosquito species, including some of those from which the virus was isolated in nature, are capable of transmitting the virus by their bites. Epidemiological studies showed that in South America sporadic cases of yellow fever occur among people whose occupation takes them into the forests. The epidemiological cycle of this *jungle yellow fever* in South America involves the reservoir monkey hosts, which infect the arboreal forest mosquitoes. These monkeys are not a permanent reservoir, as they have only a transient viremia of a few days during which mosquitoes can be infected by feeding upon them. A stable monkey population therefore, soon becomes immune, and mosquito infections die out. The virus passes through the monkey populations in epizootic waves. The mechanism of migration is not well understood; monkeys do not seem to range widely, but there is contact between neighboring populations. Furthermore, the hardy forest mosquitoes, capable of flying from one forest patch to another. The rapid extensions over long distances, and dry-season survival remain unexplained. The mosquitoes which act as vectors of the virus to the monkeys are species of *Haemagogus*, especially *capricorni*, *H. spegazzinii spegazzinii*, and *H. spegazzinii fulco*. Other species may be involved, but their role is not yet understood. The *Haemagogus* mosquitoes have a dark bluish, metallic coloration. The larvae are found in water collected in tree holes in trees and other plant cavities. The adults are arboreal in their habits, feed during the day upon monkeys and other animals living in the trees so that ordinarily people going into the forest are not attacked by the insects in great numbers. However, when the trees are cut down the mosquitoes appear at ground level in numbers and attack the wood cutters; thus, it has been stated that in parts of South America yellow fever is almost an occupational disease. Persons contra-

The infection accidentally in the forest may carry the virus to urban areas where the *man-aegypti*-man cycle may supervene.

**Jungle Yellow Fever in Africa.** In Africa, the arboreal monkeys also serve as so-called reservoirs, and the virus is transmitted to them by *Aedes (Stegomyia) africanus*, which also lives in the forest canopy and feeds upon animals resting in trees (Smithburn and others, 1949). It is interesting to note that during the course of the studies leading to the incrimination of *A. africanus* as a vector, this mosquito could not be captured off monkeys kept in cages in trees, but that it did bite monkeys kept on leashes on open platforms. The former monkeys were protected from yellow fever, while the latter became infected. *A. africanus* bites at night, when the African natives do not enter the forest; thus, there would seldom be an opportunity for the insect to cause an infection in man. However, species of monkeys susceptible to the virus descend from the forest canopy to raid banana plantations near native dwellings. Here they come into contact with *Aedes (Stegomyia) simpsoni*, which is nocturnal about habitations and breeds in plant axils. This mosquito acquires the virus by feeding upon the marauding monkeys, and in turn transmits it to man. A *man-simpsoni*-man or a *man-aegypti*-man cycle may then set in.

**Prevention.** The eradication of classical urban epidemics has been accomplished through control of *Aedes aegypti*. This mosquito is intensely domestic, and so is readily controlled through elimination of tin cans and other unnecessary artificial water containers in and around houses, the periodic emptying of flower bowls, and the like, and the use of fish or insecticides in cisterns and other large water storage tanks. The residual sprays are extremely effective against the adults of this household mosquito. As noted above, at present eradication programs are underway through much of South America. Thus there is little likelihood of the further occurrence of *aegypti*-transmitted urban outbreaks (Theiler, 1948). Control of jungle yellow fever is a more difficult problem. At present neither the reservoir monkeys nor the forest species of *Haemagogus* can be attacked successfully. It appears that the disease will remain a threat, especially to rural populations within the endemic zones, for many years to come.

**Vaccination.** Protection of individuals and whole populations may be obtained through vaccination with attenuated virus. Two strains of the virus are used for this purpose, the French neurotropic and the 17 D strains. The latter was accidentally produced through cultivation of yellow fever virus in tissue culture. The vaccine is produced by inoculation of the virus into chick embryos; after four days' incubation at 37° C the embryos are ground to a pulp, desiccated, and stored in nitrogen-filled ampules. Before use, sterile saline solution is added to the dried material, and 0.5 ml. is injected subcutaneously. Only one injection is necessary. Present evidence indicates that the 17 D vaccine confers immunity for at least six years.

The French method of immunization consists of suspending a vaccine of infected dried mouse brain in a solution of gum arabic and applying this to the scarified skin. Sometimes dried vaccinia virus is mixed with the yellow fever vaccine. This method is discussed in detail by Peltier (1948). In Costa Rica and Nicaragua a number of fatal cases of encephalitis followed the use of the French vaccine, and the Pan American Sanitary Bureau recommends the use of only the 17 D vaccine in the Americas (Yellow Fever Conference, 1955).

## DENGUE

LLOYD E. ROZEBOOM, Sc.D.

Dengue is an acute mosquito-borne fever due to a filtrable virus. The disease is characterized by sudden onset, initial erythema, headache, and pains in the trunk and limbs, especially the joints. The pain and stiffness of the joints causes a characteristic waddling gait; hence, the name dengue. The fever is of short duration and may show a saddleback curve. The pulse is slow, there is a marked leukopenia, a terminal rise, and slow convalescence. The primary rash comes during the first day or two. A secondary rash appears about the fifth day and may be maculopapular or scarlatinous in form. In some epidemics the lymph nodes are involved. Often the disease manifests itself as a mild fever lasting from one to three days, unaccompanied by a rash. Dengue is practically never fatal, but a few deaths have been attributed to it. The pathological picture has been described as including degenerative changes in the liver, kidneys, heart, and brain, and hemorrhages in the endocardium, myocardium, pleura, peritoneum, mucosa of the stomach and intestines, muscles, and central nervous system (Melissinos, 1937).

The virus is in the blood during the febrile stage. This has been demonstrated by injecting volunteers. The incubation period is variable. In experimental infections produced by infected mosquitoes, it ranged from 4 to 10 days, and when produced by injection of blood, 2 to 15 days. Several strains of the virus have been adapted to mice (Sabin, 1948).

An attack is followed by an immunity to that particular strain of the virus which may last for two years and possibly longer. Among the several immunologic types of virus there appears to be at least one common antigen which causes a partial immunity to heterologous strains for periods of two to eight months. Sabin believes that since two or more immunologic types of virus may coexist in a given area, the occurrence of the mild, atypical cases of dengue which are seen during some epidemics may be due to reinfections with heterologous strains. These mild cases are caused by non-infecting mosquitoes.

**Transmission.** The first person to transmit dengue by the bites of mosquitoes was Graham in 1903. He reported transmission with *Culex fatigans*, but as subsequent work showed that the species cannot transmit, Graham must have had

specimens of *Aedes aegypti* among his mosquitoes. Ashburn and Craig in 1907 demonstrated the infective virus in the circulating blood of dengue patients, and reported what appeared to be successful transmission to humans by *C. fatigans*. Ireland and others (1916) transmitted dengue by *A. aegypti*; the ability of this species to act as a vector was further proved by the experiments of Chandler and Rice (1923), Siler and others (1926), and Simmons and others (1931). The dengue patient is infectious to the mosquito 6 to 18 hours before the onset of symptoms and during the first three days of the disease. Mechanical transmission by interrupted feedings of large numbers of mosquitoes is possible, but ordinarily the insect cannot transmit until 8 to 14 days have passed. During this extrinsic incubation period there is a multiplication of the virus until it is possible for transmission to be effected by the bite of the insect. Once infective, a mosquito remains so the rest of her life, provided the temperature does not drop too low. Blanc and Minopetros transmitted the virus with *A. aegypti* 174 days after the mosquitoes had taken their infective blood meal. Simmons and others (1931) showed that a single mosquito could cause the infection.

The above authors also demonstrated that *A. albopictus*, a semidomestic mosquito of the Philippines and other parts of the Orient and closely related to *A. aegypti*, is also a vector. Another *Stegomyia*, *A. scutellaris*, has been suspected on epidemiological evidence for outbreaks in the New Hebrides, and Mackerras has shown this species capable of transmission by the bite. Rosen, Rozeboom, Sweet and Sabin have transmitted the virus by the bites of *A. (S.) polynesiensis*. Koizumi, Yamaguchi, and Tonomura in 1917 reported transmission with *Armigeres obturans*, but the accuracy of this finding has been questioned because the experiments were carried out in an endemic area in Formosa. Negative results were obtained by Sabin and Jahnes with several species of *Aedes* distantly related to the *Stegomyias*, with species of *Anopheles*, and with *Culex pipiens*. The most important vector of dengue is *Aedes aegypti*, while *A. albopictus*, *A. scutellaris* and *A. polynesiensis* may be involved at times.

**Epidemiology.** The epidemiology of dengue, therefore, ordinarily is similar to that of urban yellow fever, involving a man-*aegypti*-man cycle. The disease attacks both sexes and all ages. It is largely confined to cities, showing little tendency to spread to rural areas and villages. It is endemic in the tropics, but extends into the warm subtropic belt and occasionally into temperate regions. All who visit those parts of the tropics or subtropics where *A. aegypti* is still prevalent are likely sooner or later to contract the disease.

Outbreaks of dengue occur with explosive violence and may disable community after community. At Austin, Texas, in 1885, it is estimated that 16,000 out of 22,000 population were attacked; at Cairo, Egypt, in 1880, four fifths of the people are said to have suffered with the disease; in Galveston, Texas, in 1917, it is estimated that one half the population suffered, and in 1922, 60 per cent. Whole army units have been disqualified by the disease.

As there is no hereditary survival of the virus from one generation of mosquitoes to another, it would appear that the disease can maintain itself permanently only in areas where mosquitoes are active throughout the year and where there is a continual supply of susceptible people supplied by births. However, there is some evidence that there may be an extrahuman cycle, similar to that of jungle yellow fever. In-

apparent infections can occur in several species of monkeys, and *A. albopictus* and *A. scutellaris*, which can exist in the bush (and possibly other forest-species *Stegomyia* not yet tested as potential vectors), could act as carriers of the virus from monkey to monkey.

**Control.** The control of dengue epidemics is a counterpart of that of urban yellow fever. It depends upon the control of *Aedes aegypti*, and what has been said about the control of this species also applies to dengue. Where *A. albopictus*, *A. scutellaris* and *A. polynesiensis* are vectors, control measures must include the elimination of these species. Their larvae may be found in tin cans or other artificial water containers about houses, but they are usually found in coconut husks, bamboo stalks, and other small collections of water in plant cavities in coconut groves or bush away from houses. Residual DDT in houses will protect the people from bites by *A. aegypti* and the other *Stegomyias* within houses, but would seem to have little value in preventing infection by the species feeding in the bush. Air spraying by airplanes should be effective against the latter. Sabin suggests that dengue vaccine, produced from virus modified by mouse passage, "may prove to be useful in the control of epidemics and for troops or those who have to move from non-dengue areas into endemic zones." There is no specific drug treatment.

### MOSQUITO-TRANSMITTED FILARIASIS

GILBERT F. OTTO, Sc.D.

Of the several Filarioidea of man only *Wuchereria bancrofti* and *W. malaya* are transmitted by mosquitoes. The clinical term filariasis is most commonly applied to these infections. They are the species associated with the development of elephantiasis. The more common of the two, *W. bancrofti*, will serve as the basis for discussion. This form is of historical interest, also, since it was with this infection that Manson, in 1879, first demonstrated the mosquito transmission of a disease-causing organism.

**Life Cycle.** The adult worms, both males and females, are found coiled in the lymphatics, usually in the deep lymphatics of the inguinal and pelvic regions. They, with a very thin, shell-like membrane, develop into precociously active embryos in the uterus of the female and are discharged into the lymphatics and make their way to the blood stream still enveloped in the membrane or sheath which has been stretched with the growth of the embryo. These embryos, known as microfilariae,

re 250 to 300  $\mu$  long and scarcely as large in diameter as an erythrocyte; neither the alimentary canal nor the reproductive system is developed in this stage. Once in the circulation, the microfilariae may live for weeks or months, and apparently some as long as a year. In most areas of the world where this infection occurs, the microfilariae show a well-defined nocturnal periodicity in the peripheral circulation. They are most plentiful in the peripheral circulation from about 10 P.M. to 2 A.M. and except in very heavy infections may not be found at all at midday. This nocturnal periodicity may be reversed, sometimes within a week, to a diurnal periodicity by reversing sleeping and active periods of the patients. This appears to have been a factor in the reported reversal of periodicity by therapy.

In a number of Pacific Islands there is a variety or strain of this worm, in which there is no sharply defined periodicity, either nocturnal or diurnal. Furthermore, this form does not appear to develop readily in the species of mosquitoes which is one of the best vectors of the periodic variety. Accordingly, it has been suggested that it is a distinct species.\* However, it seems preferable, until more precise information helps resolve the matter, to distinguish the two as the periodic and non-periodic forms of *W. bancrofti*.

The microfilariae of both forms are incapable of further development unless they are ingested by appropriate species of mosquitoes. In the mosquito, the embryo continues its development, without multiplication, in the thoracic muscles; 10 to 40 days are required for this development. The resulting third stage, or infective larvae, migrate to the head and are ready to enter the proboscis sheath when the mosquito feeds again. Little of the development is known following the entrance of infective larvae into man. Apparently, however, there is some migration, since partially developed forms may be found in the upper extremities in a few months, whereas most of the mature worms appear to become established in the lymphatics draining the lower extremities. Not until about 18 months after infection do the next generation of microfilariae appear in the peripheral circulation. Apparently, the adult worms do not live more than 5 to 10 years.

**The Disease.** Early in the course of the infection, before the worms have matured, various degrees of lymphangitis and lymphadenitis occur. Generalized adenopathy is not common but tends to be restricted to one limb, one leg or one arm: in Samoa, the mumu, as it is called, seems to involve the arms more than the legs. Unilateral funiculitis or epididymitis may occur at this time but often it is not manifest with the first attack of mumu. Later attacks more frequently involve the lower limbs and the genitalia. Subsequent infections and reinfections stimulate the same responses, often with increasing severity as the subject becomes more sensitized. Filarial hydroceles are comparatively common in some areas. The degree of the sensitization is indicated by the fact that skin testing with as little as 0.01 ml. of 1:8,000 dilution of filarial antigen may induce an acute exacerbation of the mumu. No significant permanent damage results from the initial infections nor even from a considerable number of reinfections and superinfection. However, when the subject continues to be exposed to infection for many decades, the increasing inflammation and fibrosis of the lymph nodes, with recurrent edema, results in cellular infiltration of the edemic areas with permanent tissue enlargement. In most endemic areas

\* Ashburn and Craig in 1906 gave the specific name *philippinensis* to the nonperiodic form and Manson-Bahr in 1932 coined the specific name *pacifica* for the same form.

even the beginning of such enlargement is rarely seen before the third or fourth decade of life and conspicuous elephantiasis is seen only in a few of the older subjects. Secondary bacterial infections probably play a part, at least, in some cases both in acute exacerbations of lymphangitis and in lymphadenitis. The fact that it may be impossible to demonstrate microfilariae in the blood of advanced cases of elephantiasis has led to considerable confusion and the suggestion that such conditions are of bacterial origin. Grace and Grace apparently think that streptococcal infections are the essential cause of the elephantiasis. Most workers agree that this interpretation exceeds the available facts. Nevertheless, in Samoa, where *Staphylococcus aureus* was found as the secondary invader in filarial abscesses, penicillin without filaricidal agents frequently relieved the acute episodes promptly. The available evidence indicates that the primary cause of the elephantiasis is recurrent infections with the worm over decades but that secondary bacterial infections may contribute to the ultimate pathology. To discount the role of the filariae as the basic cause of elephantiasis because microfilariae cannot be demonstrated in these advanced cases would be comparable to denying the malarial origin of splenomegaly when malaria parasites cannot be concurrently demonstrated in the blood.

Too much stress has been placed on elephantiasis. This is the end result of the disease in comparatively few individuals. Recurrent attacks of filarial fever or malaria are far more prevalent, at least in the Pacific Islands, and afflict adults of all ages as well as not infrequently adolescents, and children occasionally. These attacks are characterized by fever, often over 102° F, and localized erythema and swelling with marked tenderness in one or more extremity or the scrotum and inguinal lymph nodes. They may last from a day or two to more than a week. Chyluria occurs in all phases of the disease but is more pronounced in advanced cases.

Transients, such as military personnel, have little to fear in terms of ultimate elephantiasis but they may suffer from filarial fever. Among the American Marines on Samoa the fear of elephantiasis and impaired sexual potential among both infected and associated personnel constituted a psychological hazard far greater than the actual medical risk. However, too great emphasis, in the field, on minimizing the dangers could decrease cooperation in prevention and permit an even higher attack rate, thereby increasing the medical problem, the immobilization of personnel in sick bay or hospital, and perhaps increase the chance of permanent damage.

**Geographical Distribution.** Periodic filariasis due to *W. bancrofti* is widely scattered in the tropics. It is, however, rarely found in the highlands. It is common in tropical Africa, southern Asia from India to China and in the islands near the Asiatic Coast from the Philippines to northern Australia and as far east as the Solomons and New Hebrides. It has been introduced into the Western Hemisphere and now constitutes a problem in some of the Caribbean Islands, including Puerto Rico and St. Croix, and in parts of South America, particularly along the Caribbean Coast. It has been introduced elsewhere in this hemisphere but has had difficulty in becoming established in North America. For instance, the only known center in the United States, at Charleston, South Carolina, has apparently completely died out without any concerted or specific attempts at control.

**Transmission.** Throughout its range it is effectively transmitted only by the domestic night biting mosquitoes, *Culex quinquefasciatus* (= *C. fatigans*) appears to be the most important vector throughout most of its range, i.e., the Western Hemisphere.

hemisphere, most of southern Asia and the western Pacific Islands and even in part of Africa. Development has been traced in about 75 other species of mosquitoes but epidemiologically most of them appear to be relatively unimportant. The ubiquitous *Aedes aegypti* may play a part in transmission where it is particularly plentiful but, in general, it appears to be less effective than *C. quinquefasciatus*. The close relative of the latter, *C. pipiens pallens*, appears to be important in part of the Yangtze delta in China. The malaria vectors appear to be important filaria vectors also in some areas, viz., *A. gambiae* in Africa, *A. punctulatus* complex in the Solomons, New Hebrides, New Guinea, and the Celebes, and *A. darlingi* in Brazil and British Guiana.

Nonperiodic filariasis occurs endemically in the south Pacific Islands east of the 170th Meridian, Fiji, Gilbert and Ellice Islands, Samoa, Tokelau, Tonga, and the Marquesas (Tahiti). Throughout this range transmission is by daytime feeding mosquitoes, *Aedes tongae* in Tonga and *A. pseudoscutellaris* throughout the rest of its range. *C. quinquefasciatus*, the most important vector of periodic filariasis, is at least an ancillary vector of the nonperiodic form and there is some evidence that it is refractory (Jachowski and Otto, 1955).

In general, more favorable conditions for transmission are required to maintain endemicity of *W. bancrofti* than to maintain malaria in a community. A greater density of mosquitoes appears to be necessary to produce highly endemic filariasis than to produce a severe malaria problem. Furthermore, filariae appear to be even more susceptible to lower temperatures than is malaria. Thus filariasis has a much more restricted distribution than malaria and is largely confined to limited areas of the tropics.

**Diagnosis.** In endemic areas diagnosis is largely clinical. The characteristic filarial fever or the terminal elephantiasis leaves little room for doubt. Microfilariae may be detected in the blood of most of those suffering the recurring attacks of filarial fever but they are detectable in only a small portion of those with advanced elephantiasis. Furthermore, since the early attacks of filarial fever may occur before the worms have completed development, it is impossible to find microfilariae on such occasions. Nevertheless, it is desirable to check the blood of microfilaria. The amount of filariasis in a community is best determined by blood examinations.

In areas where periodic filariasis occurs blood should be collected at night for examinations; for nonperiodic filariasis the time of examination is relatively unimportant but there may be some advantage in examining daytime blood. The fresh unclotted drop of blood may be examined directly to detect the active wiggling microfilariae. When fresh examination is not feasible, thick smears, as in malaria, are most commonly used. A concentration technic is also valuable when feasible. Knott's technic is best known. Freshly drawn venous blood is diluted in 10 volumes of 2 per cent formalin and allowed to stand overnight. The sediment is examined for microfilariae either unstained or stained with Loeffler's methylene blue. More rapid lysis of blood is obtained with equal volumes of 2 per cent saponin and the microfilariae which remain alive and active are more easily detected (Harris and Summers, 1945).

Intradermal tests, using antigen made from the dog filaria (*Dirofilaria immitis*), may reveal evidence of infection when microfilariae cannot be detected. Such tests may cause an acute exacerbation of filaria fever. Most workers report a high degree of specificity but cross reactions with intestinal worms have been reported.

**Prevention and Control of Periodic Filariasis.** Since this variety is transmitted by night-biting mosquitoes, infection may be prevented by remaining within screened quarters at night and particularly sleeping behind screens or under a bed net. Spraying such quarters to destroy any mosquitoes which penetrate the barriers should contribute to the protection. For this purpose a residual spray is of value but for immediate protection a space spray such as pyrethrum offers distinct advantage. Repellents may also be of value.

The ultimate eradication or even significant control is as yet to be demonstrated. The best results so far have been obtained by Brown and Williams (1949) at St. Croix, the Virgin Islands. Four applications of 200 mg. of DDT per square foot every four months resulted in over 50 per cent reduction in the number of mosquitoes (*C. quinquefasciatus*) collected in the houses and about 75 per cent reduction in the percentage of mosquitoes infected with any stage of the parasite. What is most significant is that none of the mosquitoes after this period contained parasites which had developed to the infective stage. Thus, transmission appears to have been interrupted. There is also some further evidence that transmission had been interrupted, since fewer young children were microfilariae-positive two years after initiation of spraying than were the same age groups before spraying.

In British Guiana, however, Giglioli (1948) found that the application of DDT at intervals of six months or more, which eliminated malaria and its principal vector (*A. darlingi*), had relatively little effect on the principal vector of filariasis, *C. quinquefasciatus*.

It may be that the more frequent application of DDT used by Brown and Williams would result in even more effective control if continued for many years. Since the developmental period of the parasite in man is about 18 months and the developed parasite discharges microfilariae into the blood for years, the actual value of such a program cannot be determined with certainty for years. It is at once evident that residual spraying has considerable promise but that heavier and more frequent applications will be required to destroy these mosquitoes than the similarly domestic anophelines. Not only are the culicine mosquitoes, in general, less susceptible to DDT than are the anophelines but some species of the former have developed resistant strains. To what degree this might complicate long-term use of DDT against *C. quinquefasciatus* is as yet unknown. Thus, residual spraying offers some hope for the control of this infection but the attack on the larval stages cannot yet be abandoned as a major control procedure.

*C. quinquefasciatus* utilizes a wide variety of shaded and partially shaded fresh water. It is a very domestic mosquito and like *Aedes aegypti* readily uses such artificial and domestic waters as those in cisterns, tanks, tin cans, old tires, defective eaves, and a variety of such waters, as well as natural water collections. As in yellow fever control, screening wells and cisterns and the elimination of unnecessary collections of water in artificial containers will eliminate the problem in urban areas and may be significant in many suburban and rural areas.

**Prevention and Control of Nonperiodic Filariasis.** Nonperiodic filariasis is transmitted primarily by mosquitoes which feed in the bush during the day. While they do enter houses, this is common only when the houses are within or adjacent to the bush; they do not tarry in the house and apparently never rest there. Aquatic stages are usually found in small collections of water in tree holes, co-

hells, fallen banana leaves and even artificial containers, such as old cans or bottles in the underbrush. Residual spraying or even screening, except when the house is close to the bush, offers little promise of control. Aerial spraying with DDT has promptly reduced the adult mosquito population in Samoa but had little or no effect upon the aquatic stages so that the adult population was restored to prespraying densities within two weeks. However, since it requires nearly two weeks for the microfilariae to develop to the infective stage in the mosquito, transmission was interrupted. Repetitions of such spraying at approximately two-week intervals over a six-month period produced significant reductions in the mosquito population. Thus, such spraying is of distinct military value but its possible practical value in terms of benefits to the indigenous population is still unknown.

At the present time, the only technic which offers significant protection is the clearing of the bush and destruction of likely water containers by burning or burying. Clearing the bush around habitations is significant because it destroys the harborage of the adult mosquitoes and reveals possible water containers which might otherwise be overlooked. To these may be added the destruction of tree holes by draining, felling, or elimination of the trees. These technics have protected civilian and military personnel living under urban or semiurban conditions. The program is being extended to native villages in several of the Pacific Islands. This does not protect either the native or the immigrant, civilian or military, whose activities take him into the uncleared areas during the daytime.

**Therapy.** In view of the difficulties in mosquito destruction, consideration has been given to the possible value of therapeutic means of destroying the microfilariae reservoir in the indigenous populations, both for periodic and nonperiodic filariasis. Hetrazan will quickly destroy the microfilariae but, to provide freedom from the circulating microfilariae for even six months to a year, the drug must be taken daily for two to four weeks. Field studies have shown that this is possible in limited populations but there has been no demonstration that this has provided any long-term reduction in transmission rates. Certainly, it would require follow-up observations for many years to adequately evaluate such a procedure. Repeated treatments would probably be required at intervals of less than a year to effect significant reduction in transmission. Similar experiences with malaria are not encouraging. However, the difficulties in mosquito destruction and the likelihood that the threshold of transmission is at a higher mosquito density than is the case with malaria in many areas, leads to a recurring consideration of such therapy as at least an adjunctive measure. It is, however, still a theoretical consideration.

Two therapeutic agents have been introduced since World War II, hetrazan and arsenamide (Kenney and Hewitt, 1949; Otto and others, 1953; Hawking and others, 1950). Only the former may be given by mouth and thus is the only one available for mass therapy. Its action on the adult worm is slow and uncertain. At least 2 mg./kg. t.i.d. for 30 days are required to give any assurance of successful destruction of adult worms. Arsenamide can be given only intravenously but 1 mg./kg. daily for 15 days appears to destroy the adult worms.

Individual treatment includes surgical repair of hydroceles and the removal of the elephantoid tissue of the scrotum. Surgical repair of elephantoid limbs is less successful but compression bandages may give some relief here. Penicillin may promptly relieve attacks of filarial fever but there is no evidence that it will cure the

basic condition. Bacterial abscesses may develop during attacks of filarial fever as a result of filaricidal therapy. These may require lancing, treatment with penicillin, or both.

**WUCHERERIA MALAYI.** Biologically, this infection is not materially different from the periodic form of *W. bancrofti*. Earlier suggestions that this infection produced elephantiasis of the upper extremities more commonly than in the lower extremities appear to have been completely denied. Thus, pathologically and clinically the disease, sometimes called Brug's filariasis, is similar to that produced by *W. bancrofti*. The infection has a more limited and even more spotted distribution and is transmitted by mosquitoes of the genus *Mansonia* (*Taeniorhynchus*) (*M. annulifera*, *M. longipalpis*, *M. indicans*, and *M. indiana*), although both *Anopheles hyrcanus sinensis*, and *Aedes aegypti* are reported to be capable of transmitting it. This is the principal filarioidea in Malaya; west of there it is reported from local areas of Assam, northern India and south into Ceylon. North and east of Malaya it is reported from Indochina, south China, Sumatra, Java, Borneo, Celebes, and New Guinea. The *Mansonia* are reported to be night-biting anthropophilous mosquitoes which freely enter human habitations. They should, therefore, be susceptible to residual sprays. The larval stages are attached to submerged vegetation and in North Travancore (India) Sweet and Pilai report control of *annulifera* by repeated hand picking of the water plant, of the genus *Pistia*, to which the larval stages are attached.

#### ONCHOCERCIASIS

GILBERT F. OTTO, Sc.D.

Onchocerciasis is characterized by conspicuous subcutaneous nodules on parts of the body in which the bones lie close to the surface. Thus, they are commonly seen on the head, parts of the shoulder and pelvic girdles, over the ribs and the knee and elbow joints. The nodules are the end result of the inflammatory response around the adult Filarioidea, *Onchocerca volvulus*, which are ultimately killed within the thick fibrous capsule. These nodules range in size from barely palpable to as large as a walnut. The microfilariae apparently hatch in utero and escape as naked, unsheathed, precocious embryos. They quickly leave the nodule

ut usually do not migrate far and can easily be detected in skin biopsies in the vicinity of the nodules. Nodules on the face are particularly dangerous since the microfilariae from these commonly find their way to the eyes, resulting in transient or permanent blindness. The microfilariae may find their way to the lymphatics and have been reported in the viscera but do not enter the blood stream. It has been suggested that those microfilariae which appear to have migrated more than usual result from unencapsulated adult worms but this has not been demonstrated. It is evident, however, that some worms do develop without obvious evidence of encapsulation since microfilariae may be discovered in the skin of individuals with no discernible nodules. In 1950, C. K. Becker reported finding such worms in three cases in Africa, one while doing a caesarean section, others in repairing two hernias.

**Geographical Distribution.** Onchocerciasis has a very limited and spotty distribution in the African and American tropics. In Africa, the disease is largely confined to central and west Africa from Sierra Leone and French Sudan around the Gulf of Guinea to French Equatorial Africa and the Belgian Congo; and east across the continent to the Anglo-Egyptian Sudan, Uganda, the western part of Kenya, Tanganyika, and Nyasaland. As high as 90 to 95 per cent infection, with detectable nodules, has been reported from some communities in the Belgian Congo, French Equatorial Africa, and adjacent territories.

In the Western Hemisphere, the disease is largely confined to the Pacific slope of Guatemala and southern Mexico (Chiapas and Oaxaca). In these areas, it is confined to elevations between 2,000 and 4,500 feet (Strong and others, 1934). Within this limited locality, however, 30 to 100 per cent of the workers in coffee plantations are said to be infected.

Recently, the infection has been reported in eastern Venezuela (Potenza and others, 1951). This is of particular interest because very few persons have nodules but the skin biopsies are reported by Gonzales and others (1950) to have revealed about 25 per cent infection rates in some communities. Apparently, the disease has remained undiscovered so long because of the absence of nodules.

**Transmission.** The life cycle of this worm is essentially the same as that of *L. bancrofti* except that black flies (Simuliidae) rather than mosquitoes serve as intermediate hosts. *Simulium damnosum* and *S. neavei* are the African vectors and *S. ochraceum*, *S. metallicum* (*S. avidum*), and *S. callidum* (*S. mooseri*) are the common vectors in Guatemala and Mexico. Vargas and Reyes (1949) found that *S. exiguum* is also a potential vector in Mexico. *S. metallicum* is believed, on epidemiological grounds, to be the principal vector in Venezuela.

The larvae and pupae of these flies are found attached to stones or submerged vegetation in stream beds, particularly where shallow water becomes well aerated by tumbling over rocks. The adults are strong fliers and feed readily in the daytime but may feed, to a lesser extent, at night. They attack humans viciously in the open but usually do not enter houses.

**The Disease.** The tumors are benign and only rarely is there secondary bacterial invasion or suppuration. They are, of course, disfiguring, can be very inconvenient, and are sometimes very painful, particularly when attached to the fascia covering the bones. The ocular disturbances are the most significant. Such disturbances, leading to impaired vision or complete blindness, are caused by microfilariae which have migrated from nodules on the head or face. The microfilariae may enter and even

be plentiful in the aqueous humor and can often be readily seen with the slit lamp. This condition is particularly common in Guatemala and Mexico where the nodules are found principally on the head. It occurs also in Africa but is much less common since the nodules there are more frequently on the body or extremities.

**Prevention, Control and Treatment.** The wearing of clothing and head nets, fly areas will offer protection. Repellents may also serve this purpose. Neither, however, appears to offer significant community control. Since the flies rarely enter houses, spraying the house has little or no value against this disease. The attempts to spray vegetation, although theoretically of value, have not had any demonstrable effect. Destruction of aquatic stages of the flies in the streams has been difficult but Garnham and McMahon (1947) have succeeded in eliminating *S. neavei* from a valley near Nairobi in Kenya by the use of a constant drip of DDT upstream from the breeding sites. Similar use of DDT and gammexane (benzene hexachloride) is said to hold promise in Mexico.

Treatment as a means of reducing the microfilaria reservoir has been considered but there is no evidence so far that it has any significant value. In the treatment of the individual, Burch recommends Bayer 205 (Suramin). Hetrazan by mouth quickly destroy the microfilariae and produce a severe allergic reaction followed by improvement in the ocular manifestations. Hawking and Laurie (1949) report that the adult worms are not killed by Hetrazan; thus, improvement appears to be only temporary. The possible dangers of massive destruction of microfilariae in the eye by this or any drug have not been fully explored. Surgical removal of the nodules is effective.

#### OTHER FILARIOIDEA

GILBERT F. OTTO, Sc.D.

Of the other Filarioidea, *Mansonella ozzardi*, *Acanthocheiloneima perstans*, *A. streptocerca*, may be dismissed without discussion since they are not associated with any clear evidence of disease. Brief mention may be made of *Loa loa*.

Loiasis occurs endemically only in limited areas of central and north Africa. Infection rates as high as 15 per cent have been established by the examination of a single blood smear in the south part of the Anglo-Egyptian Sudan. It is common in parts of the Belgian Congo and French Equatorial Africa; it has roughly the same geographical distribution as *Onchocerciasis* in Africa, except that it does not extend as far south of the equator as the latter. It appears to be the common

larioid infection contracted by missionaries and other white immigrants in Africa.

The adult worms live a free and migratory life in the subcutaneous tissues and on occasion migrate beneath the bulbar conjunctiva and even into the superficial layers of the cornea. The microfilariae are sheathed and must be distinguished from those of *W. bancrofti*. They are found in the circulating blood both night and day but they have a definite diurnal periodicity, being somewhat more plentiful at noon than at any other time. Transmission is by the tabanid flies, *Chrysops dimidiata*, *C. placea*, and perhaps *C. distinctipennis*. These flies feed in the daytime and attack man in the open but do not enter houses.

Although the adult worms may often be easily seen as they raise the skin on moving, no pain or swelling is evident at these locations. Even their presence in the eye is often without material disturbance beyond the shadows they cast in the visual field. However, transient but recurring swellings, commonly known as Calabar swellings, are characteristic of the disease. These are apparently of allergic origin and there is some suggestion that desensitization takes place after decades of infection in the native population. Calabar swellings are particularly common in infected Europeans and Americans. The swellings result from subcutaneous edema; they are nonpitting and rarely inflamed. They may occur on any area of the body but are characteristically seen on the ventral surface of the wrists and the palms of the hands. They are frequently seen on the ankles also. The swollen eyelids are more conspicuous but less common. There is no tendency for the swellings to be localized in the vicinity of the adult worm. Eosinophilia of 20 to 40 per cent is common.

**Prevention and Treatment.** The only prevention is protection from the bites of flies by use of protective clothing or insect repellents. Such measures are difficult to maintain constantly. No community-wide control programs have been developed.

When the worms are readily detected they may be surgically removed. Hetrazan, which has been tried against a number of filarioids, is perhaps the most effective against this worm. It appears to be the drug of choice; Shookhoff and Dwork (1949) found that as little as 0.1 gm., t.i.d., for 10 days was effective in some cases but in others the treatment might have to be repeated. This is less than the 2.0 mg./kg. used as the individual dose in other filarioid infections. Since the drug itself is relatively nontoxic, it may be preferable to raise the dose to 2 mg./kg., t.i.d., for 5 days.

### THE ARTHROPOD-BORNE VIRUS ENCEPHALITIDES

HENRY W. KUMM, M.D., DR.P.H.

During the past two decades much information has been assembled concerning a group of disease processes which have caused epidemics of encephalitis in man. Hammon (1948) suggested that the term "arthropod-borne virus encephalitides" would be an appropriate name to apply to this rapidly growing collection of pathological entities. Insofar as is known at present, all of them are transmitted in nature either by insects or acari and all of them are caused by filtrable viruses.

They include four diseases encountered in the Western Hemisphere, two from the Orient and one from Africa. Among the former, eastern, western and Venezuelan equine encephalitis should be mentioned as well as St. Louis encephalitis. The oriental maladies comprise Japanese B and Russian (Far Eastern) tick-borne encephalitis. The most recent addition is West Nile encephalitis, which was discovered in 1937 by Smithburn and his associates in Uganda, East Africa. There are indications also that louping-ill of sheep may belong in the same group.

In man, these diseases are characterized by a sudden onset with headache, fever, chills, nausea, vomiting, generalized pains and malaise. Within a day or two marked drowsiness or stupor supervenes and a stiff neck often becomes a prominent symptom. Mental confusion, speech difficulties, tremors, convulsions and coma may develop in severe cases. A moderate degree of leukocytosis as well as pleocytosis are common laboratory findings.

In this group of diseases man is usually only an accidental host in a natural process, which functions in the complete absence of human beings. Incubation periods vary from 5 to 21 days. Japanese B and eastern equine encephalitis result in a high proportion of severe and fatal cases, while western equine and St. Louis encephalitis are more benign illnesses, at least in man.

For purposes of clarity, the etiology, distribution and epidemiology of the seven disease entities will be considered individually.

#### ST. LOUIS ENCEPHALITIS

Between July and November, 1933, approximately 1,100 cases of encephalitis were registered in the city and county of St. Louis, Missouri. In this epidemic there was no particular race or sex prevalence and multiple cases in the same family were rare. The incidence of cases in the county in proportion to population was thirteen times as great as in the city. Fatality rates approached 20 per cent.

The virus nature of this disease was soon discovered by two independent groups of investigators. Mice proved to be more susceptible than rhesus monkeys to intracerebral inoculation. Pathological changes consisting of a meningo-encephalitis were more evident in the cerebral cortex than in the basal ganglia or midbrain.

Reeves (1948) states that outbreaks of, or immunity to, St. Louis encephalitis have been encountered in the states of Arizona, California, Missouri, New Mexico and Texas, as well as in the Belgian Congo and Kenya Colony. Mixed epidemics of St. Louis and western equine encephalitis are common in the western United States. Both viruses were isolated from wild mosquitoes caught in the Yakima Valley of the State of Washington.

In order to confirm the diagnosis in a human case it is necessary either to isolate the virus or to make serological tests of paired specimens of sera collected in the acute and convalescent stages of the disease. If antibodies against St. Louis virus are absent from the first specimen and present in the second, it may be concluded that the patient has had St. Louis encephalitis. With regard to the isolation and identification of the virus it should be pointed out that the active agent has not been recovered from the spinal fluid of human beings and only rarely from the blood. If the patient dies, the virus may be recovered from brain or spinal cord tissues.

It was early suspected that mosquitoes might be responsible for transmission and this supposition was shown to be correct when Hammon and Reeves (1934) found naturally infected specimens of *Culex tarsalis*, *Culex pipiens* and *Aedes*

*orsalis*. The species of arthropods which have been found infected in nature with the seven types of encephalitis included in this discussion are listed in Table 6-2.

Table 6-2. Species of arthropods found naturally infected with encephalitis viruses

### A. MOSQUITOES

Species of Mosquito	Type of Encephalitis						
	St. Louis	Western Equine	Eastern Equine	Venezuelan Equine	Japanese B	Russian Tick-borne	West Nile

The seasonal incidence of St. Louis encephalitis is characteristic, most cases occurring in the late summer and early fall. This observation led Hammon and Reeves (1943) and numerous other investigators to make studies of the potentialities of many kinds of mosquitoes as vectors of the virus. Fifteen species have been shown

experimentally to be capable of transmitting St. Louis encephalitis by bite to suitable animals.

Up to the present time, however, only two species of *Culex* and one of *Aedes* have actually been incriminated under natural conditions. As a source of virus for infecting mosquitoes, chickens are superior to mammals, though chickens do not become chronic carriers. In the Yakima Valley, Hammon made numerous precipitin tests with *Culex tarsalis* and he found that about half of those tested had fed on birds. *C. pipiens* also preferred bird blood though *A. dorsalis* fed more readily on horses.

As transovarian passage of the virus does not occur in any species of mosquito, an explanation is needed of how the disease survives the winter season. No virus was isolated from more than 5,000 hibernating specimens of *C. pipiens* and *C. tarsalis* tested in Washington. Blattner and Heys (1944) have secured experimental transmission with the American dog tick, *Dermacentor variabilis*, but there has been no evidence suggesting that ticks are actually implicated in nature.

A more promising line of investigation appears to be that of Smith and others (1944), who isolated St. Louis encephalitis virus from chicken mites, *Dermanyssus gallinae*, during a nonepidemic period in St. Louis. Neutralizing antibodies found in young chickens living in an area where human beings were not developing the disease, suggested that some blood-sucking vector, which did not bite man, was transmitting the virus among fowls. In 1948, these same workers were able to show that chickens bitten by infected *D. gallinae* circulate virus in sufficient concentration to infect other mites or mosquitoes, and that the latter could transmit the infection by bite to normal chickens or to hamsters. Transovarian passage of virus readily occurs among chicken mites. In the St. Louis area, therefore, the survival of the virus during the winter season is readily explained.

However, Hammon and Reeves (1946) have suggested that the epidemiology of St. Louis encephalitis in the Pacific Coast states may not be the same as that postulated for the endemic area near St. Louis, since more than 100,000 chicken mites have been examined by them with entirely negative results. They feel that California and Washington wild birds and their parasites may be more important than chickens and chicken mites as reservoirs for St. Louis virus during the winter months.

Both men and horses are accidental hosts. Natural immunity has been observed in a wide variety of mammals, including horses, cows, dogs, sheep, goats, pigs, rats and rabbits. Among birds which have been surveyed, immune chickens, ducks, geese, turkeys, pheasants, quail, pigeons and a burrowing owl have been found. Frequent antibodies against both St. Louis and western equine encephalitis virus have been encountered in the same animal or bird.

#### WESTERN EQUINE ENCEPHALITIS

The symptoms of this disease in horses were described by Large in 1867, but it was not until 1931 that Meyer and his associates proved conclusively that the etiological agent was a virus.

Although this is a widespread and very serious disease among horses, it is by all means confined to equines. Leake (1941) reported that 1,260 human cases occurred in North and South Dakota, 250 in Nebraska, 64 in Montana and 43

Manitoba. Eklund (1946) gave a detailed account of the 1941 outbreak in Minnesota, which involved at least 850 people. Human cases were predominantly rural and most prevalent among adult males. The case fatality rate was 9.7 per cent. Whereas poliomyelitis is essentially a disease of children, western equine encephalitis has a high incidence among the older age groups.

Reeves (1948) states that western equine encephalitis has been found in all of the western states and as far east as Michigan, Texas, and Alabama. It has also been observed in Canada and Argentina. This malady is characteristically a summer disease, the enormous Minnesota outbreak having taken place between June 21 and September 18, with a peak of reported cases early in August.

Many laboratory transmission experiments have been carried out, a dozen species of mosquitoes having been incriminated by bite.

Seven, as shown in Table 6-2, have been found infected under natural conditions, the most important being *Culex tarsalis*. Hammon and Reeves (1945) isolated the virus of western equine encephalomyelitis 75 times from *C. tarsalis* caught in the Yakima Valley, Washington, in California and in eastern Nebraska. In addition, they isolated virus twice from *Aedes dorsalis* and once each from *Anopheles freeborni*, *Culex pipiens*, *Culex stigmatosoma* and *Culiseta inornata*. The following year Norris (1946) found naturally infected specimens of *Culex estuans* near Winnipeg, Manitoba.

An unusual finding was that reported by Kitselman and Grundmann (1940) who succeeded in demonstrating the presence of western equine encephalitis virus in three out of five lots of *Triatoma sanguisuga* taken near Garrison, Kansas. Two horses pastured in the same field, where the infected cone-nosed bugs were captured, had died previously of encephalitis. *T. sanguisuga* normally live in the burrows of wild rodents and feed readily on horses. It has not yet been possible to decide whether triatomines actually play a significant role in the transmission of the disease or whether those infected bugs were merely examples of "dead-end infections."

Syvertson and Berry (1941) have shown that the wood tick, *Dermacentor andersoni*, can be infected experimentally with western equine encephalitis virus and that ticks can transmit the disease by bite to ground squirrels, *Citellus richardsonii*. Transovarian passage of the virus also occurs in this species of tick, but the actual role of ticks in nature, if any, has not yet been ascertained.

Sulkin (1945) isolated encephalitis virus of the western strain from *Dermanyssus gallinae* caught in Texas and two years later Sulkin and Izumi (1947) found naturally infected specimens of *Liponyssus bursa* in the same area. Meanwhile, in Kern County, California, Reeves and others (1947) had recovered western equine encephalitis virus from wild bird mites, *Liponyssus sylviarum* captured in the recently deserted nest of a yellow-headed blackbird. Similarly in Weld County, Colorado, Miles and others (1951) found virus in *Dermanyssus americanus* taken from the nest of an English sparrow. It appears, therefore, that whereas chicken mites have been incriminated in Texas, wild bird mites may be more important than chicken mites in California, Colorado and Washington.

Further studies of wild bird mites in California led, in 1948, to a remarkable finding which was reported by Hammon and his associates. From a collection of *Liponyssus sylviarum* they isolated a strain of virus which appeared to be either

a mixture of both St. Louis and western equine encephalitis viruses or else a "ste virus" from which those two agents had originally evolved. A final decision on the exact status of that new strain of virus has not yet been made.

Hammon and Reeves (1946) observed that chickens infected with western equine encephalitis by the bite of *Culex tarsalis* showed no sign of illness, but the circulated virus for a few days in a titer sufficiently high to infect other mosquitoes. This temporary viremia in chickens was followed by a firm immunity. Horses which had been infected by mosquito bite did not circulate enough virus to infect normal mosquitoes. The basic cycle, therefore, was one involving birds and mosquitoes while men and horses were merely accidental hosts. The true reservoirs appear to be various species of bird mites.

An investigation into the bionomics of *C. tarsalis* in relation to western equine encephalitis was carried out by Jenkins (1950). He reported that *C. tarsalis* was very common west of the Mississippi River from Canada to Mexico, its distribution being quite similar to that of western equine encephalitis in horses. That species of mosquito attained its maximum abundance between July and September, the preferred hosts being wild and domestic animals and birds but not man. *C. tarsalis* fed readily at dusk or at night and had a flight range of up to two and a half miles. Some of the adults mate in the fall and females can overwinter in protected places. *C. tarsalis* were unusually abundant in the summer of 1941 when a severe epizootic of equine encephalitis swept across the northwestern states.

In addition to horses the virus of western equine encephalitis has been isolated from a prairie chicken, red winged blackbirds, a magpie and a deer. Neutralizing antibodies have been found in horses, mules, cattle, pigs, sheep, goats, dogs, rabbits, mice, a weasel and a chipmunk. Among the birds, natural immunity has been encountered in chickens, ducks, geese, turkeys, pheasants, partridges, quail, pigeons, doves, woodpeckers, robins and the burrowing owl.

Formolized vaccines of various types have been recommended for immunizing animals. The possibilities of control of the arthropod vectors should be carefully considered, wherever these are known.

### EASTERN EQUINE ENCEPHALITIS

Eastern equine encephalitis was first recognized as a distinct disease entity in 1930. Three years later two different groups of investigators reported the isolation of the causative agent from horses. During an extensive epidemic in eastern Massachusetts in 1938 the virus was also obtained from man. At that time the case fatality rate in horses was about 90 per cent, while 25 out of 38 known human cases died. Children seemed to be particularly vulnerable.

Ten Broeck and others (1935) called attention to serological differences between the viruses of the eastern and western types of equine encephalitis. The seasonal incidence of the two maladies, however, was quite similar, eastern equine encephalitis also being a disease of the late summer, reaching its peak of prevalence in September. Epizootics among horses were studied in New Jersey, Delaware, Maryland, and Virginia, and it was noted that the distribution of equine cases was closely related to the salt marsh areas, infections appearing in contiguous flocks without any actual contact having taken place between the sick animals. It

observations such as these which suggested that the disease might be carried by mosquitoes.

According to Reeves (1948), eastern equine encephalitis has been found in most of the eastern states and as far west as Michigan and Texas. It has also been identified from Argentina, Brazil, Canada, Cuba, Mexico, Panama, and Venezuela.

The incubation period in a horse is about four days and virus may circulate in equines before the onset of fever. This illness is not primarily an infection of horses, but, as in the case of western equine encephalitis, both horses and men serve only as accidental hosts. The true reservoir hosts are various species of domestic and wild birds and their parasites. Chickens and turkeys after superficial inoculation of a small amount of infectious material will show high titers of virus in the blood for several days followed by the appearance of neutralizing antibodies. Eastern equine encephalitis virus has been isolated from sick pheasants, and recovered birds have been found to be solidly immune.

Table 6-2 indicates that two species of mosquitoes have been incriminated in nature. Howitt and others (1949) recovered virus from *Taeniorhynchus perturbans* (*Mansonia perturbans*) captured in Burke and Jenkins Counties, Georgia, during an epizootic of encephalitis among horses. More recently in Louisiana, Chamberlain and his colleagues (1951) obtained infected *Culiseta melanura* near where an infected purple grackle had been shot.

Feemster and Getting (1941) studied the distribution in eastern Massachusetts of six of these potential vectors. They were prevalent throughout the summer months and reached their peak of abundance in September. Feemster and Getting concluded that *A. vexans* was probably the most important of them, at least during the 1938 epidemic in Massachusetts, because it was extremely common and because it was found wherever the disease had occurred.

Howitt and others (1948), working at Shelbyville, Tennessee, isolated the virus of eastern equine encephalitis from chicken mites and chicken lice, *Dermanyssus gallinae* and *Eomenacanthus stramineus*, respectively. Immune horses, cows and chickens were found in this area. This observation suggested the possibility of a fundamental reservoir mechanism in chickens and chicken parasites similar to that which has been postulated for St. Louis encephalitis by Smith and others (1948) as a result of studies carried out near St. Louis itself.

In spite of the severity of the average attack, a certain number of human beings and horses may become immunized with little or no clinical reaction. Birds generally have an asymptomatic viremia, though one epizootic was described among pheasants, which was characterized by a mortality rate of 22 per cent. Formalin-inactivated vaccines prepared from infected chick embryos have been recommended for preventing the disease in animals.

#### VENEZUELAN EQUINE ENCEPHALITIS

Venezuelan equine encephalitis is a serious disease of horses which has been identified from Colombia, Ecuador, Panama, Trinidad, and Venezuela. In human beings it generally causes only a mild illness though two fatal infections were reported in 1943 from the island of Trinidad.

In 1935, an extensive epizootic was studied among horses and mules in

Colombia and three years later the virus was isolated by Beck and Wyckoff in Venezuela and differentiated from other members of this group.

Gilyard (1944) captured naturally infected specimens of *Taeniorhynchus titillans* (*Mansonia titillans*) in Trinidad and he also transmitted the disease to a normal donkey with mosquitoes of this species. In addition, the virus has been transmitted in the laboratory by *Aedes geniculatus*. The reservoirs of this disease in nature are still to be found.

### JAPANESE B ENCEPHALITIS

This name has been used by Japanese workers to distinguish the oriental insect-borne type of encephalitis from Von Economo's disease or encephalitis lethargica. Cases were first observed in 1871 and a very severe epidemic broke out in Japan in 1924. It was not until 1936, however, that the virus was definitely identified by Kasahara, Kawamura, Taniguchi and their co-workers.

In Korea and Okinawa, Japanese B encephalitis has recently posed a serious problem for the occupying troops. Many local children have been infected as well as some of the military personnel. It has also been identified from Guam, the Philippines, China, Formosa, Korea, Malaya, and Siberia. Australian X disease or Murray Valley encephalitis appears to be very closely related to Japanese B encephalitis.

Pathologically, this disease produces a meningo-encephalitis, the structures most severely affected being the thalamus, substantia nigra and the gray matter of the cerebral cortex. Tissue from the central nervous system is the best type of material from which to attempt to isolate the active agent.

Japanese B encephalitis is a summer disease. Males are attacked more frequently than females. Only two species of mosquitoes have so far been found infected in nature. Hammon and others (1949) isolated the virus from a pool of *Culex tritaeniorhynchus* collected in a cow barn in the Okayama prefecture of Japan. They pointed out that the seasonal prevalence and geographical distribution of this species made it highly suspected. No virus was obtained by those workers from *Culex pipiens*. However, Mitamura and others (1939) reported that they had obtained naturally infected specimens of both *C. tritaeniorhynchus* and *C. pipiens pallens* from that same region.

Many laboratory transmission experiments have been carried out both with oriental and with occidental species of mosquitoes. Seventeen species have been found to be capable of transmitting the virus by bite.

Chickens have not been implicated in the epidemiology of this disease in Japan but house finches, following minute inoculations, do circulate virus in amounts sufficiently large to infect mosquitoes. This virus also has been found to circulate in horses, pigs and goats, two strains having been isolated recently from the brain tissue of horses. Sabin and others (1947) reported that natural immunity had been found in horses, cattle, pigs, goats, and rabbits, but not in chickens. They suggested that arthropod vectors other than mosquitoes might serve to maintain the virus during nonepidemic years. Evidences of natural immunity to Murray Valley encephalitis have been found in Australian cormorants, herons, ducks and swans.

Various types of immunizing agents have been prepared, including mouse-brain

and chick-embryo vaccines. The response to initial vaccination is moderate and transitory, though revaccination is said to produce more striking serological changes. The protective value of these vaccines has not yet been determined.

#### RUSSIAN (FAR EASTERN) TICK-BORNE ENCEPHALITIS

Russian (Far Eastern) encephalitis was first observed in 1932 as a springtime disease, which principally attacked persons who were working in the uncleared virgin forests of Siberia. More recently, it has also been reported from European Russia, Austria, Bohemia and Moravia. Silber and his associates isolated the virus in 1937 (Silber and Soloviev, 1946). Mice can be infected by intranasal, intravenous or subcutaneous inoculation but the intracerebral route in mice appears to be the most efficient method.

The clinical picture is not unlike other types of encephalitis except for a residual paralysis of the brachial plexus and muscles of the neck which is said to occur in more than 20 per cent of recovered patients. A drooping head gives these patients a very characteristic appearance. Mortality rates vary from 2 to 15 per cent. Sera collected from convalescent cases within 30 days or more of recovery neutralize the virus.

The annual peak of human cases occurs in May or early June. Men from 20 to 30 years of age are more commonly attacked than women. The patients have usually not been in contact with one another and mosquitoes are not present in those regions at the time of the appearance of the first cases each spring. Secondary cases do not occur in nearby urban areas.

The virus has been isolated from naturally infected ticks of the species *Ixodes persulcatus* and transovarian transmission has been demonstrated. Infected ticks have been obtained after hibernation and before they had fed on any animals in the early spring. Two other species of ticks have been infected in the laboratory, *Dermacentor silvarum* and *Haemaphysalis concinna*.

The etiological agent has been isolated from the brain of several fatal human cases and also at times from the liver, spleen, spinal cord, and blood. Two strains of virus were obtained from wild chipmunks. The Amur hedgehog, *Erinaceus amurensis*, is susceptible experimentally and has once been found infected in nature. That particular infected hedgehog was heavily parasitized by *Ixodes persulcatus*. No final conclusion has been reached concerning the principal animal reservoirs of this disease.

Immunologically, the viruses of Russian tick-borne encephalitis and louping-ill are closely related. Japanese B and St. Louis encephalitis also show a certain degree of group relationship, but western equine encephalitis is quite separate and distinct serologically. Smorodintsev (1956) has prepared a formalin-inactivated vaccine which is said to give some protection against Russian encephalitis.

#### WEST NILE ENCEPHALITIS

West Nile virus was originally isolated by Smithburn and others (1940) from the blood of an African woman with fever who was examined during a survey of the West Nile District of Uganda. This neurotropic agent is related immunologically to the viruses of St. Louis and Japanese B encephalitis. It is pathogenic for monkeys and rodents when inoculated intracerebrally.

Natural immunity to West Nile virus is widespread among the human population of Egypt, the Sudan, Kenya Colony, Uganda and the Belgian Congo. In an endemic area situated in the delta of the Nile, strains of virus were isolated from the blood of two pigeons and a crow.

Two species of mosquitoes, *Culex antennatus* and *Culex pipiens*, are able to transmit the virus by bite under laboratory conditions and the former has on several occasions been found infected in nature. In addition natural infection was demonstrated by Taylor and Hurlbut (1953) in three pools of mosquitoes containing specimens of both *C. pipiens* and *C. univittatus*.

## AFRICAN TRYPANOSOMIASIS

*(African Sleeping Sickness)*

GILBERT F. OTTO, Sc.D.

African trypanosomiasis is a chronic infectious disease caused by flagellates (Protozoa) of the genus *Trypanosoma*. On the basis of morphology and biology, the many species which have been described from mammals fall into a limited number of more or less distinct groups. The organisms causing African sleeping sickness belong to the *brucei* group which includes three forms, commonly considered as three species, but which are morphologically indistinguishable one from the other:

*T. brucei*: cause of Nagana in equines; also infects cattle, in Africa.

*T. gambiense*: cause of most of the sleeping sickness of man in Africa. Man serves as the only significant reservoir.

*T. rhodesiense*: cause of a more fulminating type of the disease in man. Very spotted in its distribution.

There is not complete agreement on the taxonomic position of these forms but there appears to be growing support for the postulate that *T. brucei* of wild ruminants, and now a common cause of disease in domestic cattle and equines, is the parent form.

Thus, *T. gambiense* is considered to be a variety of this species which is in the process of evolution into a new species. It has apparently already evolved to the place where it has largely lost its capacity to infect equines and ruminants, has gained the capacity to readily infect man, and in nature is transmitted by different species of tsetse flies than are utilized by *T. brucei*. Certainly, as a matter of convenience,

particularly to avoid confusion in terminology, it seems desirable for the present, at least, to retain the name *T. gambiense* for this physiological variety or species of trypanosome in man.

*T. rhodesiense* is generally believed to represent a more recent evolution from *T. brucei*, and perhaps even one that is currently evolving and not yet well established as a primary infection of man. It is separated largely on clinical and epidemiological grounds.

**Geographical Distribution.** Trypanosomiasis due to *T. gambiense* has a local and patchy distribution in tropical Africa. It is limited almost entirely by the distribution of its two principal vectors, *Glossina palpalis* and *G. tachinoides*. In general, it may be said to occur between 10° north and 10° south of the equator; it extends a bit farther north to Gambia and Senegal on the west coast but is scarcely found north of the equator on the east coast. The most highly endemic areas are along the Congo River and its tributaries in the Belgian Congo and French Equatorial Africa. Trypanosomiasis does not occur in the immediate coastal areas but inland it extends up to at least 3,500 feet elevation.

Trypanosomiasis has been carried by infected individuals to various parts of the world, but particularly to America in infected slaves. Nevertheless, in the absence of the appropriate vector, it has never become established anywhere outside tropical Africa. Within Africa it has continued to spread into new areas with migrations and development of new settlements, and epidemic outbreaks have occurred within the past decade. The introduction of the disease into a community where tsetse flies exist or the movement of noninfected immigrants into an endemic area is associated with a high mortality rate. In the endemic areas, as with malaria, reasonably good health for most of the populace is provided by immunity purchased at the price of a high mortality rate.

**Life Cycle.** The trypanosomes are slender, leaf-shaped or spindle-shaped extracellular parasites ranging in size from 15 to 35  $\mu$  long by 1.5 to 3.5  $\mu$  wide. They move rapidly with the aid of a conspicuous undulating membrane, which terminates in a single anterior flagellum. Upon staining with one of the Romanov's stains the large central nucleus and the smaller posterior kinetoplast are easily seen as red objects within the blue cytoplasm. Within the cytoplasm darker blue or purple volutin granules may be seen. Only this stage is known in man; it divides by longitudinal binary fission. Early in the course of the infection these trypanosomes may be found in the blood stream but later in the lymph nodes and still later in both the lymph nodes and the cerebral spinal fluid.

**Transmission.** Although prenatal infection and mechanical transmission by interrupted feedings of biting flies are both possible, neither plays any significant role in the epidemiology of the disease. Transmission is dependent upon tsetse flies (*Glossina*) in which there is biological development and multiplication of the parasites. The trypanosomes after ingestion by the fly undergo retrograde development to the crithidia or crithidiform stage as it multiplies by transverse binary fission in the midgut. After about 10 days they start growing back to the trypaniform stage and at the same time migrating toward the head end. About 20 days after the fly has become infected the so-called metacyclic trypanosomes are found in the salivary glands ready to infect man when the fly feeds again. These metacyclic trypanosomes

are somewhat more slender and the undulating membrane is less well developed than in the mature trypanosomes found in man.

*T. gambiense* is transmitted throughout most of its range by *Glossina palpalis* but *G. tachinoides* is an important vector in some areas, notably northern Nigeria, and *G. pallidipes* appears to be the principal vector in Uganda. *T. rhodesiense* is apparently transmitted primarily by *G. morsitans* but *G. swynnertonii* and *G. pallidipes* serve as vectors of local importance. *G. morsitans* is also the principal vector of *T. brucei*.

**Biology and Ecology of the Tsetse Flies.** The tsetse flies flourish only within a comparatively narrow range of temperature and humidity. The optimum climatic conditions appear to be afforded by 25° to 30° C (about 75° to 85° F) with 40 to 60 per cent relative humidity. Many die at temperatures above 35° C and few survive 40° C. Thus, during the hot dry seasons in the northern part of their range dense shade is indispensable for survival. On the other hand, when there is a very high relative humidity there is very little reproduction. The flies are ovoviviparous or larviparous. One larva matures at a time in the uterus and a total of 8 to 10 larvae are usually produced. The larvae immediately burrow into loose protected soil, often beneath stones or logs, and pupate. The pupal stage lasts from 20 to 40 days. Like the adults, the pupae are very susceptible to extremes of temperature and humidity. They are killed equally well by drying or by being constantly wet. Thus, the temperature and moisture requirements of both the adults and pupae largely restrict them to areas close to streams and lakes bordered by a heavy cover of tree or brush or both. The several species have their own precise requirements within these broad limits. *G. palpalis* prefers the heavy deciduous forests with heavy underbrush along rivers and lake shores. It does not persist in the dense evergreen forests. They must have high and fairly dry ground for pupation and do not survive in low wet areas. These flies are well adapted to feeding on man and domesticated animals. They will follow a possible blood meal for miles in the cover but do not venture far into the open. *G. tachinoides* survives better in less densely wooded areas and extends into the wooded savannahs of northern Nigeria. Although this species withstands hotter and drier climates than does *G. palpalis*, during such periods it is also concentrated in the more densely shaded riverine forests. *G. morsitans* is a woodland savannah species which also concentrates in wooded areas near water during the drier seasons; at other times, however, it roams widely over the more open grasslands. It appears to prefer wild game for food but readily feeds on domestic equines and ruminants and will attack man.

All species are daytime feeders primarily but will apparently also feed on bright moonlit nights. They rarely enter houses. Both males and females feed and transmit the infection.

**The Disease.** The flies bite so painlessly that the victim may be totally unaware of the attack. Later, however, the site may become indurated, erythematous, painful and, when subsiding, leave evidence of a lymphangitis. Sometimes the trypanosomes may be found in the skin shortly thereafter. In general, this is followed by an incubation period of weeks or months. The disease may be conveniently differentiated into the septicemic and neurotropic stages. The septicemic stage may last for months and is characterized by recurring bouts of remittent fever with headache and

lymphadenopathy. The most common suggestive sign is the characteristic enlargement of the postcervical chain; the nodes are soft but non-suppurating and painless. There may be evidence of toxic encephalitis and myocarditis; tachycardia is sufficiently frequent during this stage to be highly significant. Parasites can frequently be detected in the blood during the septicemic stage. This stage is not critical in uncomplicated trypanosomiasis. The neurotropic stage of the disease is ushered in with various neurological manifestations. Fever is less frequent and the lymph nodes gradually become fibrosed, and atrophy. Anorexia is common and the resulting malnutrition is believed to contribute significantly to the critical and fatal course of the disease. The troubles of this stage concern various cerebral functions and are by no means constant. They include aphasia, ataxia, personality changes, attacks of Jacksonian epilepsy, and paralysis agitans. These often do not develop for years in *T. gambiense* trypanosomiasis. The final stages are characterized by increasing attacks of somnolence, often with periods of nocturnal excitement. Cachexia usually develops before the patient becomes comatose and dies.

Trypanosomiasis due to *T. rhodesiense* develops much more rapidly. Parasites are more plentiful in the blood, adenopathy is less pronounced and there is little distinction between the septicemic and cerebral stages of the disease. It may run a fatal course in six months.

**Laboratory Diagnosis.** Most workers agree that microscopical examination of material aspirated from the lymph nodes is the most satisfactory method of detecting the parasites. Broden found 87 per cent of his verified cases by this method. Included in his series were cases without palpable nodes. The material may be examined fresh to detect the active trypanosomes or may be stained with one of the Romanovsky stains. Examination of the blood is usually considered unsatisfactory in *T. gambiense* infections but is more commonly positive in *T. rhodesiense* infections. However, there have been reports of finding the trypanosomes readily in thick smears and in centrifuged blood. Examination of the spinal fluid is practically much less than formerly. It appears to have some value late in the disease when the lymph nodes may be fibrosed and the parasites are principally in the central nervous system. Culturing, animal inoculation, and serological tests have been considered but their place in routine diagnosis is yet to be established.

**Prevention and Control.** (Buxton, 1948; Davey, 1948; Bequaert, 1946; Nasir, 1948a and b.) Personal protection includes avoiding the "fly areas" in the daytime, using repellents and protective clothing, and, so far as possible, traveling at night in fly areas.

Community-wide control has taken three basic courses: (1) direct attack on the fly; (2) maintaining a fly-free barrier; and (3) prophylactic treatment. The quarantine principle has been applied to some degree, at least, in connection with all these. In the *T. rhodesiense* and *T. brucei* areas the systematic destruction of game has also been practiced for the dual purpose of destroying the reservoir of infection and destroying the principal source of food for *G. morsitans*.

The direct attack on the fly has taken several forms but the destruction of suitable cover is perhaps the most common procedure, particularly in west Africa. For this purpose it is not necessary to destroy the forest but merely to clear the underbrush and in some cases thin the large timber. In some areas of Nigeria this has been facilitated by controlled burning. Burning not only destroys the cover for

dult flies but at the same time heat-kills the pupae. Despite its advantages for tsetse fly control it may prove to be ecologically undesirable in the long run and is perhaps less practiced now than formerly. Furthermore, burning the brush in *G. morsitans* territory may result in heavy grass growth which can actually improve some areas for this species. While destruction of forest cover for the flies is visualized as a means of attacking the fly, the same principle is used as a protective procedure. In the development of the Anchan rural resettlement in Zaria Province of Nigeria, a corridor 10 miles wide was cleared of fly breeding from the Zaria-Kano railway to the Zaria-Jos line 70 miles away. Resettlement was within this corridor and lines of communication could be traveled to the two railways in safety (Nash, 1948a). Similar provisions have long been made on a much more limited scale in protecting European developments in tropical Africa. Often it is sufficient for reasonable control to clear the immediate area in which living and working activities are carried on. Considerable success has resulted from clearing the brush and trees for a hundred yards or more around ferrying points, and even fording and bridge approaches to streams in the tsetse fly belt.

In some areas of Nigeria significant reduction in the fly population has resulted from the hand catching of flies by native boys. Trapping flies has also proved useful. Insecticides have not proved useful either in destroying the flies or interrupting transmission of the disease. Since the introduction of residual spraying both DDT and benzene hexachloride (gammexane) have been used in aerial spraying without much success. Periodic spraying and dipping of cattle to kill the attacking flies have also been tried without too much success.

Chemoprophylaxis is promising in prevention. Experimentally, a single dose of Bayer 205 (Surinam) appears to offer complete protection for at least three months thereafter and the more recently introduced pentamidine appears to offer such protection for at least six months (van Hoof, 1947). Accordingly, the use of these drugs is now a routine procedure in many areas, to at least supplement other control procedures. In some areas, notably the Belgian Congo, the use of these drugs, particularly pentamidine, has been administratively developed into a primary control procedure. Pentamidine is administered intramuscularly every six months in doses of 2 to 3 mg./kg.

A number of drugs, including Bayer 205 and pentamidine, appear to be therapeutically effective during the septicemic stage of the disease but so far only tryparsamide is dependable in the treatment of advanced cases of the disease.

## AMERICAN TRYPANOSOMIASIS

(Chagas Disease)

GILBERT F. OTTO, Sc.D.

American trypanosomiasis, or Chagas disease, results from the accidental infection of man with *Trypanosoma* (*Schizotrypanum*) *cruzi* which appears to be a more common parasite of lower animals. The results of serological tests suggest that most human infections are benign or asymptomatic but in some areas, at least, it can produce serious disease. The parasite was first discovered by Chagas in 1909 in the insect vector, *Panstrongylus* (*Triatoma*) *megista*, and only later discovered in man and other mammals.

**Life Cycle.** In man and other mammals the parasite is known to exist in two stages, the trypanosome or trypaniform stage in the blood stream and the intracellular leishmania or leishmaniform stage, commonly in endothelial cells or the myocardium. The leishmaniform stages are oval and about 1.5 to 4.0  $\mu$  long and are indistinguishable from the parasites of the genus *Leishmania*. The trypaniform stage is characteristically bent into a C or U shape, is about 15 to 20  $\mu$  long, and can easily be distinguished from *T. gambiense* by the very large kinetoplast, which may even appear to extend beyond the limits of the cytoplasm in the stained specimen. Multiplication is by binary fission primarily in the leishmaniform stage. Rapid repeated divisions result in nests of these leishmaniform stages in the cell which give the suggestion of schizonts. It was this appearance that led to the name *Schizotrypanum*. The insect vector acquires the infection, apparently the trypaniform stages, by feeding on infected animals or man. Development in the insect is similar to that of *T. gambiense* except that the metacyclic trypanosomes ultimately are found in the hind-gut rather than in the salivary glands.

**Transmission.** Mayer, in 1918, reported that the bugs may remain infected for two years. The bugs characteristically defecate as they bite and in 1938 Cardo showed that the metacyclic trypanosomes from the feces of the bug were able to become established in experimental animals by penetrating the normal mucous membrane or the abraded skin. They did not succeed in penetrating the normal, intact skin and there was no transmission by biting. There is no pain associated with the actual feeding of the bug but an intense itching may develop as the proboscis is withdrawn. It is assumed, therefore, that human beings become infected through the mucous membrane, commonly the palpebral conjunctiva, or through scratching the parasites in the feces of the bug into the wound in the skin.

*Panstrongylus megista* is the principal vector in Brazil; *Triatoma infestans* in Argentina, Bolivia, Chile, and also important in Brazil; *Rhodnius prolixus* in Venezuela; and *Triatoma dimidiata* in Central America. *T. hegneri* and *T. gerstaeckeri* have been reported infected in Yucatan, Mexico. In the United States, at least eight species of the genus *Triatoma* have been reported naturally infected in Texas, Arizona, and California. *T. rubrofasciatus*, which is widely scattered in the Western Hemisphere and the Orient, has been found infected with the erithidia or erithidiform stages of flagellates indistinguishable from those of *T. cruzi*, but Floch and Abonnec, in French Guiana, and Deane, in Brazil, have shown that these erithidiform stages of *T. conorrhini* of the rat.

**Animal Reservoirs.** The infection has been found in a wide variety of wild and domesticated animals. These include the armadillo, opossum, ferrets, foxes, rats, and other small rodents, and one species of monkeys, as well as the dog, cat, and pig in South America. The opossum appears to be one of the commonest of the reservoirs but recently Neghme and Román (1948) found 13 per cent of the dogs and cats in Chile infected as compared to less than 2 per cent of the wild animals examined. In the United States the wood rat, as well as the opossum and armadillo, has commonly been found to be infected. In view of the report of *T. conorrhini* in rats, data obtained by xenodiagnosis should be reviewed.

**Geographical Distribution.** The demonstrated infection appears to be most common in man in southern Brazil, Uruguay, and across Argentina to Chile. Neghme and Román found 12 per cent of the rural population in central Chile positive on xenodiagnosis and 17 per cent positive on serological test. In Argentina up to 23 per cent has been reported. Human infections appear to be less common in the northern part of South America but have been reported, and the infection is comparatively common in animals. Up to 15 to 20 per cent human infection is reported in Bolivia. Only a few rare human infections have been verified in Central America and Mexico but serological tests in Panama suggest that it is not uncommon. No natural human infections have been reported in the United States but Packchanian (1943) infected a human volunteer with the flagellates from naturally infected *T. heidmanni* in Texas.

**Disease.** Apparently, most infections in man are harmless and asymptomatic. Difference in the severity of disease may well be, in part at least, a reflection of strain differences in the parasites (Hauschka and others, 1950). However, clinical cases have been reported from various areas of South America. While they appear to be more frequent in southeastern Brazil and northern Argentina, there are an increasing number of such reports from Venezuela, Bolivia, and other countries in northern South America.

The commonest early sign of the infection is a conspicuous swelling of the lids of one eye. It may be that when infection is through abraded skin rather than through the mucous membrane, the local reaction is so slight as to be overlooked. In Packchanian's experimental infection, by putting feces from an infected bug in the left eye, the lids of that eye became swollen, hyperemic, and painful in two weeks, reached its maximum severity by the eighteenth day and subsided in two more days. This was accompanied by a low-grade fever and enlargement of the axillary nodes; fever persisted for two weeks and nodes less than two months. Parasites were demonstrated in the blood from 21 to 84 days after infection. No cardiac disturbances were reported and the patient required no therapy. Apparently, many natural infections are no more severe but there is an increasing number of reports of cases with evidence of severe myocardial damage. Recent reviews by Torrealba (1946), in Venezuela, and Ponde (1948), in Brazil, stress the necessity of considering cardiopathy in Chagas disease and considering the possible causative relationship of *T. cruzi* to myocarditis in the endemic areas. Earlier suggestions that they may cause serious pathology of the thyroid have not been confirmed.

**Laboratory Diagnosis.** The parasites can be detected in the blood of human beings for only a short time. Inoculation of blood into culture media or laboratory animals is some improvement over direct examination. However, the best method

for actually detecting the parasites is by xenodiagnosis. In this test, laboratory-reared *Triatoma* are allowed to bite the individual to be examined and the crithidiform stages are recovered from the feces of the bug after multiplication. Deane (1947) calls attention to the fact that using this technic to survey rodents may lead to error through recovering the crithidiform stages of *T. conorrhini*. The complement-fixation reaction has been used both clinically and in surveys. Its uses and limitations have been reviewed by Hauschka and others (1950).

**Prevention and Control.** The only practical approach is through preventing attack by the triatomines. The bugs apparently have no preference for human blood but will attack man freely if given the opportunity. They find shelter in brush piles, lumber piles, or in accumulated debris. It is significant that most of the infections are in rural areas among people of the lower economic groups. Debris under and around the dwellings of such houses affords excellent harborage for the bugs; cleaning up such debris affords a large measure of protection. Neghme has found as high as 90 per cent reduction in the bugs as a result of one application of DDT but reports that benzene hexachloride (gammexane) is probably superior (see Chapter 7).

No therapeutic agent has been consistently successful so far.

**Other Trypanosomes in South America.** *T. rangeli* was originally discovered in *Rhodnius prolixus* in Venezuela and has since been reported in several other countries in South America. Pifano (1949) has recently studied the infection in humans. He reports that *T. guatemalensis* is a synonym. More recently *T. ariari* has been reported as a human infection in Colombia (Renjifo-Salcedo and others, 1949). Both *T. rangeli* and *T. ariari* appear to be quite distinct from *T. cruzi* but since both infect man and both utilize triatomines as intermediate hosts, it is not clear to what degree they have been confused with *T. cruzi* in earlier work.

Leishmaniasis exists in three rather well defined clinical forms. The causative agents, *Leishmania*, are round to oval parasites 2 to 4  $\mu$  long. They are morphologically indistinguishable from each other and from the leishmaniform stage of *Trypanosoma cruzi*. They are classified with *Trypanosoma* in the family Trypanosomidae. Three specific names are usually given to the organisms which cause the three different forms of the disease. They are distinguished by tissue preference and resulting clinical manifestations and geographical distribution. There is also a limited amount of work on serology and biology which tends to support this classification. However, it has been reported that *Leishmania* from either the cutaneous or visceral form of the disease may produce both visceral and cutaneous infections in dogs. Kirk (1949) has recently reported that a strain of *Leishmania* isolated from a human case of visceral leishmaniasis in the Anglo-Egyptian Sudan produced visceral, cutaneous, and mucocutaneous lesions in monkeys. Furthermore, a few cases of visceral leishmaniasis occur annually in South America and those areas of the Near East, India, and south China where the disease is usually in the form of mucocutaneous or cutaneous leishmaniasis. Nevertheless, it is generally agreed that there are advantages in retaining the following specific names for the diseases indicated:

*Leishmania donovani* (*L. infantum*; *L. chagasi*), the cause of visceral leishmaniasis;

*L. tropica*, the cause of cutaneous leishmaniasis;

*L. brasiliense*, the cause of mucocutaneous leishmaniasis.

#### VISCERAL LEISHMANIASIS (Kala Azar, Dum-Dum Fever, Black Fever)

Visceral leishmaniasis is primarily an Old World infection. In the Mediterranean area it occurs principally as a disease of infants and very young children, hence the names infantile kala azar and *L. infantum*. It seems unlikely, however, that this age distribution is associated with a species characteristic. The infection occurs along the Mediterranean coast of Morocco, Tunis, and Algiers in Africa, and, in Europe, along the Mediterranean coast of Spain, a limited area of France around Marseilles, the southern tip of Italy, and a limited area of Yugoslavia east of the Trieste area, and Greece. It is also found on the Islands of Malta, Sicily, Crete, and the adjacent Greek Islands. In the Mediterranean area it appears to be most severe in Sicily and Italy. In Africa, kala azar occurs also in the Anglo-Egyptian Sudan and, to a lesser extent, in Abyssinia and northern Kenya. Adler (1947) found that the Sudan strain is biologically similar to *L. infantum* \* of the Mediterranean, despite the difference in the age groups attacked. In these areas, as in Asia, the disease occurs in adolescents and adults rather than in infants. Foci of infections occur in Transcaucasia, Turkistan, and east of the Caspian Sea to India. Although the disease is the most severe and the most widespread in India, even here it is restricted to the eastern side of the peninsula. Although it occurs as far south as Madras, the principal infection is north of the head of the Bay of Bengal in Assam, Bengal, Bihar, and the United Provinces as far west as Lucknow. It is endemic in much of this area and attacks

\* These workers retain the two specific names *L. donovani* and *L. infantum*, the latter being applied to the Mediterranean and Sudanese strains.

principally the 10 to 14 year age group. Epidemic waves occur and Napier points out that during the past half century there have been three epidemic waves in Assam and each succeeding wave has penetrated further up the Assam valley. There is no extension of the infection east of Assam and it occurs elsewhere in Asia only in China from the Yangtze Valley north into Manchuria; there have been reports of the infection in inner Mongolia. Infection in this area appears to be even less restricted to the younger age group than in India. The infection has never been reported in the Pacific east of the Asiatic mainland.

A few cases of visceral leishmaniasis occur each year in South America; the use of the viscerotome in examinations for yellow fever in Brazil and Argentina has revealed less than 0.1 per cent infection.

**Life Cycle.** Only the nonflagellated leishmaniform stage is known in mammals. It is strictly an intracellular parasite occurring commonly in the endothelial cells, various glands and organs. In some areas it is reported commonly in lymph nodes. Multiplication is by repeated binary fission. While these leishmaniform stages have been recovered from feces, urine, and nasal secretion, they are so poorly prepared to survive in the external environment that transmission by these means is usually discounted.

Epidemiological evidence has incriminated sandflies, *Phlebotomus*, but only occasional infection was established in the laboratory before Smith and his co-workers in 1941 discovered that infections would not regularly develop unless the flies were permitted to feed on plant juices after feeding on the infected man or animal; the same year Adler and Ber (1941) showed that the flies could be induced to ingest *Leishmania* from culture only if diluted with 2.5 per cent salt solution. It has since been amply established that in the midgut of the flies, as in culture, the parasites develop into the flagellated leptomoniform stage. The parasites return to the mouth parts and man is infected by the bite of the fly. *Phlebotomus argentipes* is the principal vector in India, *P. major* and *P. perniciosus* in the Mediterranean and *P. major chinensis* in China. More than a dozen species viciously attack man in Sudan but Kirk and Lewis (1947) report that only *P. langeroni orientalis* has a distribution similar to that of kala azar. Corradetti has reported that *P. perfiliewi* is a vector in southern Italy.

**The Disease.** The incubation period is generally believed to be one to three months but there are cases reported to have developed in less than two weeks after arriving in the endemic area and as long as a year and a half after leaving it. The onset may be abrupt with a malaria-like paroxysm, but more commonly with a rapidly mounting temperature or even so insidious that the patient can scarcely recognize his initial illness. Anemia and leukopenia regularly occur; the leukopenia is due primarily to a reduction in the granulocytes; a relative, and often an absolute, monocytosis occurs. There may be recurring bouts of fever and headaches for months; recurrent diarrhea is common. The spleen and liver both become enlarged and tender. In China and the Sudan, lymphadenopathy is reported to be common. Napier emphasizes that this is unusual in India. Emaciation with edema of the extremities is seen in advanced cases. Untreated cases in epidemics have been associated with 75 to 90 per cent mortality. Most and Lavielles (1947) have reviewed the clinical course of the disease in American soldiers.

Recovery from the acute phase of the disease may be followed by the app-

ence of pigmented cutaneous nodules as much as a year or more later. This is most commonly reported from India. Parasites may be detected in these nodules.

**Laboratory Diagnosis.** Detection of the parasites is not easy. The examination of the blood is particularly unsatisfactory but Napier reports that they are usually present in the blood of the clinical case and continued search should reveal them in macrophages or lymphocytes. Parasites may be more readily found in aspirates from the spleen, lymph nodes, and bone marrow. The latter is more commonly used. Any of these materials may be inoculated into culture (NNN medium) or animals (hamsters) but a month or more may be required to confirm the diagnosis. Several tests have been developed which depend upon the increased euglobulin content of the serum during the disease. The aldehyde test is the simplest; one or two drops of formalin are added to 1.0 ml. of serum and it becomes solid and opaque within a few minutes to 24 hours. The antimony tests depend upon layering a solution of one of the pentavalent antimonials (4 per cent urea stibamine in the Chopra test) over diluted serum; a flocculent precipitate is formed at the interphase.

**Epidemiological Factors.** In India, apparently there are no significant animal reservoirs but in both the Mediterranean area and in China the dog appears to be important. The flies attack man viciously in the shaded forests both day and night but in more open country enter houses to feed primarily at night. The flies pass larval and pupal stages in moist sandy soil, protected from direct rays of the sun. In nature, hollow trees and other protected wooded spots are used but the flies have become well adapted to shelter provided under houses, between buildings and in abandoned buildings. The disease is almost entirely rural or semirural but excursions into villages or margins of larger cities are common.

**Control.** Attempts to attack directly the diffusely scattered breeding spots does not appear to be feasible. DDT spraying of houses has been reported to be highly effective in the destruction of *Phlebotomus* in Abruzzi, Italy (Corradetti, 1949), and in preventing the transmission of infantile kala azar there. This use of residual sprays has apparently not been extensively employed in India and China and arguments have been advanced against its chances of success there. However, since it has been successfully used to control phlebotomi which transmit pappataci fever in the Mediterranean area and American leishmaniasis and bartonellosis in Peru, it seems probable that residual spraying has not had sufficient trial against kala azar. The flies are so small that screening of houses and the use of bed nets offer relatively little protection unless a very fine mesh is provided.

Isolation and treatment are considered to be significant control procedures in India.

A number of pentavalent antimonials are effective but a long course of treatment is required; these include neostibosan, stibanose (solustibosan), urea stibamine, and stibamidine.

### CUTANEOUS LEISHMANIASIS

(*Oriental Sore, Old World Cutaneous Leishmaniasis*)

Oriental sore is perhaps most commonly seen in the Near East and eastward into northwest India. The local names, Bagdad boil, Aleppo boil, Lahore boil, and others reflect the localized nature of the endemic areas within this broad zone. In general, the distribution is quite different from that of kala azar but the two overlap in the

Mediterranean area and in Transcaucasia and Turkestan. The disease appears to be spreading northward in the latter areas. In Africa, it is found in Egypt and extends up the Nile to Sudan but has been reported from along the Mediterranean coast as far west as Morocco. It appears to be relatively rare in Europe but Corradini (1948) has reported that it is of frequent occurrence in Abruzzi, Italy, where infantile kala azar is also common. He reports nearly 3.0 per cent with active infection and over 20 per cent with healed cutaneous scars in one survey. In the Far East the disease has been reported from south China and Indochina; a few cases have also been reported from Queensland, Australia. In general, the infection is found in drier country than is kala azar, due apparently to the fact that the principal vectors prefer the dry areas.

**The Disease.** The incubation period is not constant; it is said to vary from a few weeks to several years. The characteristic lesion is initiated as a granular nodule which ruptures into an open ulcer, usually on an exposed part of the body. The lesion may remain circumscribed and after a year or more may heal with a permanent, often disfiguring, scar. Often, however, they enlarge into the eroding type of ulcer. Multiple lesions are common and while they may result from contact, the spread to new sites is apparently usually by way of the lymphatics (Ansari and Mofidi, 1950).

Secondary bacterial infection may occur and actually kill the parasites so that the characteristics of a pyogenic lesion develop.

**Laboratory Diagnosis.** The organisms can usually be detected by smears made from the base of the ulcer; it is essential to get beneath the necrotic tissue to live cells in obtaining material for the smears. Steinhauer has recently reported that an interdermal test will detect up to 97 per cent of the cases.

**Transmission and Epidemiology.** The infection is transmitted biologically by *Phlebotomus* in the same manner as kala azar. In the Mediterranean area, the Near East and India the principal vectors are *P. papatasi* and *P. sergenti* but *P. macedonicum* has also been incriminated in Italy. The infection in the Near East is most common among the poor, being particularly common among the beggars. It is possible that contact infections may occur or that it may be transmitted mechanically by flies which swarm on the sores under these circumstances. However, the organisms appear to be unable to penetrate the skin and would have to reach an abrasion. Certainly, the infection is not maintained in the absence of the biological vector, *Phlebotomus*.

Dogs serve as a reservoir of infection near human habitations and particularly in village or urban areas. Wild rodents, particularly the gerbil (*Rhombomys opimus*), serve as the reservoir in rural areas. Since the sandflies commonly live in the burrows of these rodents they have a high infection rate in such places and are to be avoided.

**Control, Immunity, Treatment.** Upon recovery from the infection, either spontaneous, or as a result of therapy, the individual is usually thereafter immune. Recognition of this centuries ago resulted in the local practice in certain areas of the Near East of deliberately inoculating newborn babies with material from open ulcers. Apparently there was sufficient prenatally acquired immunity to prevent extensive ulceration and sufficient infection developed to subsequently protect the individual. This has not been developed into modern public health practice. However, A.

and Zuckerman (1948) have found that when phenolized parasites from culture are inoculated and followed by living organisms from culture, a localized and transient immunizing infection results. So far, a highly protective immunity has resulted only from infections. Since it may be necessary to treat the immunizing infections the procedure has not been given extensive public health trial.

Residual spraying with DDT should have value, particularly in localized community infections in villages.

Pentavalent antimonials are effective both topically and intravenously. Trivalent antimonials appear to have the greatest value when applied topically.

#### MUCOCUTANEOUS LEISHMANIASIS

(*American Cutaneous Leishmaniasis, Espundia, Chiclero Ulcer*)

Although mucocutaneous leishmaniasis has been reported in the Old World, notably in the Anglo-Egyptian Sudan, the designation is usually given to the disease if it occurs in South America. While the mucocutaneous lesions, particularly involving the lips or the nose, may be said to characterize the disease, they are by no means the only lesions found. In Peru, where Weiss says the disease rivals malaria, initial lesions are most commonly on the exposed skin similar to those of Old World mucocutaneous leishmaniasis. This is followed in many cases by secondary lesions or direct extension to the mucocutaneous junction. Goldman (1947) has reviewed and amply illustrated the disease. In Yucatán Peninsula, Mexico, the lesions show a peculiar distribution, occurring usually on the lobe of one ear.

The disease appears to be most common in northern Argentina, Brazil, Bolivia, and Peru but has been reported in all other countries of the northern part of South America. It has been reported from Panama but is not common and apparently does not occur elsewhere in Central America or Mexico, except on the Yucatán Peninsula where it is confined to the chiclero workers. It rarely occurs in women or children in this area. Pessôa and Barretto (1946) report that in parts of Brazil the infection is largely restricted to woodsmen. In Peru, the infection is contracted both in such areas and in villages.

Transmission is by sandflies and *P. intermedius* is common in eastern and northern South America. More work is needed to more sharply indicate the species involved. Animal reservoirs may well exist but relatively few dogs and cats have been reported infected. The wild animals have not been extensively studied.

**Control.** Hertig and Fairchild (1948) have shown that DDT will effect complete control around human habitations in Brazil. Since the flies move by a series of short, hop-like flights, even a residual outside the houses, on window sills and harborage areas, such as stone walls, will protect the occupants from infection and effect reduction in the flies. These workers point out that recovery of the fly population is slow and, thus, the results of a single spray may have long-lasting effects. The protection of the chiclero workers in Yucatán and those who work in the woods in Brazil and Peru is more difficult. Protective clothing including head nets are indicated when flies are plentiful. Repellents may be used.

As for cutaneous leishmaniasis, the antimonials are the preferred therapeutic agents.

## PHLEBOTOMUS FEVER

(Pappataci Fever, Sandfly Fever, Three-Day Fever)

LLOYD E. ROZEBOOM, Sc.D.

Phlebotomus fever is an acute specific infection, caused by a filtrable virus conveyed to man by the bite of *Phlebotomus papatasi*. The disease was described by Pym in 1804. Doerr and his co-workers, in 1909, showed that the virus was present in the blood of patients during the first day of the disease, at which time it can be picked up by *P. papatasi* females feeding upon the patient. Following an extrinsic incubation period of about five days or more, the flies are able to transmit the virus by the bite. The length of time that the flies remain infective does not seem to have been established.

The period of incubation is three to five days. The disease is characterized by sudden onset, fever lasting two or three days, headache and aches in the body. Uncomplicated cases are never fatal. The disease occurs in epidemics with a high incidence rate, and so may cause considerable loss in effectiveness among troops, laborers, and other groups of people. Clinically, it resembles influenza and dengue. Convalescence is slow, requiring three to four weeks. Diagnosis is based upon clinical and epidemiologic evidence (Sabin, Philip and Paul, 1944). Phlebotomus fever may be suspected when there is an outbreak, within the range of the vector, of illness with fever of short duration among soldiers, immigrants, or other newly arrived groups of people. Sabin's studies (1948) indicate that there are at least two strains of the virus which are unrelated immunologically. One attack by a given strain confers a solid immunity for at least two years, and possibly much longer.

Within endemic areas, adults and adolescents are largely immune; presumably this immunity is acquired by infections occurring during infancy or childhood.

Phlebotomus fever is prevalent in the Mediterranean region, the Middle East, provinces of Central Asia in the USSR, and the northwest and central provinces of India. It has been reported from Mexico, Central and South America, but so far as known at present, *P. papatasi* is the only vector and as this species does not occur in the Americas, the infections in the neotropical countries may have been misdiagnosed cases of atypical dengue or other febrile disorders. Experiments on the capability of other species of *Phlebotomus* to transmit this or related viruses would be of interest.

The mechanism of survival of the disease from one epidemic season to the next is unknown. The virus disappears quickly from the blood of the patient; immune persons apparently are not infectious to the flies; there are no known reservoir hosts, and survival in the adult fly is thought to be impossible because the adult is not supposed to be capable of hibernation. The winter season is said to be passed by *Phlebotomus* in the larval stage. It has been claimed by some workers that there is a hereditary survival of the virus in the flies, which would account for interepidemic survival, but Sabin was unable to obtain infected progeny from infectious females. It has been suggested that larvae might acquire the virus by feeding upon the dead bodies or excreta of infected adult flies, but other workers have observed that the larvae do not feed to any great extent upon these substances. Young and his associates found mites attached to a number of adult *P. papatasi*, and present the theory that these arachnids might be the reservoir of the virus, passing it on to the flies, which, in turn, may infect man. There is no evidence to support this hypothesis.

Treatment of phlebotomus fever is symptomatic; there is no specific therapy. Prevention depends upon the control of sandflies, especially through the use of residual insecticides in human dwellings. Protection may be obtained through the use of repellents.

#### BARTONELLOSIS

(*La Verruga, Oroya Fever, Carrión's Disease, Verruga Peruana*)

GILBERT F. OTTO, Sc.D.

Bartonellosis is an infectious disease caused by a pleomorphic bacterium, *Bartonella bacilliformis*. The disease is limited to the river valleys of both slopes of the Andes in Peru and adjacent countries at elevations from 1,500 to 9,000 feet. It is possible that the disease which beset the Spanish conquistadores in this area was bartonellosis but the first established epidemic was in 1870, when about 7,000 workmen died of the disease in the building of the railroad in the Oroya River Valley. Epidemics still occur when nonimmunes are quartered in the endemic areas. The infection was apparently introduced into Colombia in the middle 1930's, re-

sulting in a highly fatal epidemic in 1935. The disease is also reported from Ecuador.

**Vectors and Reservoirs.** The disease is transmitted by sandflies. *Phlebotomus verrucarum* is the only demonstrated vector and its distribution in Peru coincides with the distribution of bartonellosis. It is a nocturnal form and freely enters human dwellings to attack man at night (Hertig, 1942). Two other species have been found in parts of the endemic areas but appear to be unimportant. *P. peruvianus* feeds indifferently on man and animals but shows no preference for man; it frequents caves and apparently feeds on lizards. It is absent from some of the most important endemic areas. *P. noguchi* does not associate with man particularly; rarely enters either human dwellings or stables. It appears to prefer field mice and is found in caves and mouse burrows. *P. verrucarum* has not been reported in Colombia but Rozeboom (1947) found an almost indistinguishable form, *P. Colombianus*, to be the principal species present in collections from the endemic area.

No animal reservoirs have been found. Monkeys have been experimentally infected but the usual laboratory animals are refractory.

**The Disease.** The incubation period is usually three to four weeks but may be more than three months. The disease occurs in two distinctive stages, the septicemic or Oroya fever stage followed by dermal lesions or the verruga stage. The relationship between the two was not recognized until Carrión, in 1885, inoculated himself with blood from a verruga nodule and died five weeks later from Oroya fever.

The septicemic stage is characterized by headache, general malaise, an irregular remittent fever and rapidly developing anemia. The red cell count may drop below 2,000,000 in less than two weeks. This is associated with a marked enlargement of both spleen and liver; generalized lymphadenopathy is also usual. The organisms can usually be seen as rods in the red cells during this period; they may be cultured from the blood as well. In epidemics the case fatality rate is from 40 to 90 per cent. Death usually occurs within three weeks of the onset. If the patient survives three weeks, convalescence and the dermal lesions or verruga develop; the verruga may not appear for a month or more. Even in epidemics the septicemic stage may be mild as to pass unnoticed and the verruga stage alone may appear as the only obvious sign of the disease. It is a popular belief that the development of verruga assures ultimate complete recovery. The dermal lesions may be either military or nodular. Both suggest hemangioma and the nodules have a marked tendency to rupture. There may be successive crops over a period of a month or more. Organisms may be recovered from the skin lesions.

Until the advent of the antibiotics there was no satisfactory treatment. Chloramphenicol is reported to be effective (Urteaga and others, 1955).

**Prevention and Control.** Since the principal vector, *P. verrucarum*, is a nocturnal biter particular protection should be taken at night. A fine mesh bed net is required to exclude these insects. Repellents may prove more useful. He reports that since 1909 it has been the practice of the railroad company not to quarter its personnel within the endemic area at night. Since these areas are quite localized it may require moving only a few miles to a camp site free of the insect.

Hertig and Fairchild (1948) have found that DDT applied to dwellings, stables, walls, old buildings, and other man-made resting places will prevent transmission and produce a marked reduction in the fly population for a year or more.

PLAGUE

Since the dawn of history, bubonic plague has been known to be one of the major pestilences of mankind in some parts of the world. Numerous writers described the manner in which it spread in devastating epidemics. Up to the turn of the past century efforts to explain these phenomena were shrouded in mysticism and demonology or vaguely attributed to miasma, but a discriminating minority held to the idea that the disease was contagious. The association of an epidemic in human population with a concurrent high mortality enzootic among rats was repeatedly observed but its significance was not grasped.

Belief in the vital importance of the rat in plague was not generally accepted until a decade after Kitasato and Yersin in 1894, working independently, discovered the causative agent, *Pasteurella pestis*. A French epidemiologist, P. L. Simond, in 1897, reviewing the available evidence and the manner in which the disease was disseminated in Bombay, postulated the concept that bubonic plague was primarily a rat disease and that man played only a secondary part in the spread of the infection and that transmission from rat to rat and from rat to man was effected by fleas. The validity of this postulate was confirmed and its implications elaborated by other investigators. Urban plague was found to involve commensal rats and the tropical rat flea, *Xenopsylla cheopis*; rural plague (sylvatic) a variety of wild rodents and of many flea species. This did not exclude the consideration that *P. pestis* may occasionally be transmitted directly from man to man by air-borne nuclei causing epidemics of pneumonic plague nor, on the other hand, that plague infection may smolder for years in a wild rodent population with only a sporadic transmission to man.

Even after the discovery of the rat (*Rattus norvegicus*, *R. rattus*) as a reservoir host of *P. pestis* and the flea as the principal vector, the efforts of health authorities to halt the march of epidemics were singularly ineffective. The control of plague presented a problem of great complexity which required for its solution an intimate acquaintance with all the factors governing the fourfold relationship of man, microbe, rat and flea. The prevalence of plague in any particular community is affected by the habits of a variety of rodents and their fleas, and they in turn are influenced by climate, harvest, and a number of other changes in environment.

**Plague in Rats.** Where conditions are favorable for the spread of plague, sick and dying rats are often noticed some days prior to the onset of the initial human cases. Sometimes, however, the diagnosis of a human case is the first evidence that the disease is present. Under such circumstances sick or dead rats usually will be

found upon searching premises where the infection might have been contracted either the home, place of occupation or nearby premises. Many cases of plague receive their infection through handling dead rats during an epizootic of plague in ignorance of it. Sick rats apparently crave water which accounts for their being seen in the open and often dying away from their nests.

Plague among rats acts differently depending on whether it is an initial infection, also whether it is in large or small communities and upon many other factors. In small communities, where the conditions are particularly favorable, plague spreads with such rapidity that it may destroy nearly the entire rat population and then burn out for lack of material. In large cities these severe primary epizootics last long and die down but not out, and increase again in severity at later periods. With the continuance of plague in such places, as time passes there is a noticeable decrease in the number of dead rats found and also a decline in the disease in man. There is little doubt that the explanation of diminished rodent plague is directly connected with an increasing immunity of the rat population. The Indian Plague Commission found that 59 per cent of the rats in Bombay were immune to plague, whereas rats of Madras showed slight immunity. In San Francisco, McCoy also showed that 15 per cent of small rats and about 50 per cent of large rats were immune to highly virulent material.

Plague infection in rats is characterized by engorgement of the subcutaneous blood vessels and a diffuse pink color of the subcutaneous structures and muscles. The diagnosis may often be inferred at the first incision. The lymphatic glands of the neck, axilla, groin or pelvis are enlarged and frequently surrounded by a hemorrhagic exudate and edema. The liver is granular with focal necroses, the spleen enlarged and friable, and pleural effusions are common. All of this pathological picture is seldom found in a single rat.

In subacute cases or when rats are recovering from infection and resolution is taking place, often referred to as chronic plague, the pathology is somewhat different. In this type the lesions consist of purulent or caseous foci, usually in the abdominal viscera; that is, they occur as splenic nodules and abscesses, or mesenteric abscesses. Sometimes abscesses are situated in the regions of the peripheral lymphatic glands. Plague bacilli are either absent or very scanty upon microscopic examination of the abscesses, but may be recovered by cultural methods or more surely by guinea pig inoculation.

The macroscopic appearance of guinea pigs is somewhat similar to that described for rats except that the gelatinous hemorrhagic exudate and enlargement of the inguinal glands are more marked and the spleen is generally filled with small abscesses. If the guinea pig dies in four days or less the abscess condition of the spleen may not be present but plague organisms will be found in enormous numbers in the organs and the blood. When a guinea pig lives eight days or is killed on the tenth day, these findings are of the resolving type noted in rats.

**Plague in Fleas.** As observations and experiments accumulated it became evident that different species of fleas varied greatly in their efficiency as natural vectors of human plague. In any particular locality it was determined by their numbers, dispersion, rodent hosts, tendency to attack man and other factors. When a flea takes a blood meal on a rodent host with an infection in the septicemic phase

plague bacilli are introduced into the alimentary tract and find conditions in the lumen of the gut favorable to multiplication. In some flea species the mass of rapidly growing micro-organisms in the proventriculus becomes so large that additional food is blocked from passage and the flea dies of starvation. It was formerly thought that the plague organisms passed through, and infection of rodent or man resulted from scratching the flea bite and contaminating the wound with infected feces. Now it is accepted that the infected flea regurgitates the bacilli into the wound as it feeds. This blockage phenomenon is characteristic of those species that are efficient vectors of *P. pestis* (Eskey and Haas, 1940). There is no trans-arterial passage of these micro-organisms from one generation of fleas to the next.

In an infected plague focus the epidemic potential may be determined in part by the number of fleas of the vector species. Attempts have been made to standardize a quantitative index in terms of the average number per rat (Hirst, 1953).

**Sylvatic or Campestral Plague in North America.** In August, 1903, a black-footed rat died of plague contracted from a squirrel in Contra Costa County, California. In 1904, Currie demonstrated the susceptibility of the ground squirrel to bubonic plague. In 1908, McCoy and Wherry discovered natural plague in ground squirrels. It was then learned that thousands of squirrels had died of some disease during 1904, 1905 and 1906. This epizootic was doubtless plague. Since then the infection has continued endemic among the ground squirrels.

California is overrun with three species of ground squirrels, of which the commonest is *Citellus beecheyi*. They live in colonies in burrows or warrens. The screech owl which is a frequent companion in their burrows may spread infected fleas. Owls give the infection to squirrels and the squirrel flea (*Ceratophyllus acutus*) then passes the disease among them. This flea will also attack man just as do rat fleas. The infection may also be conveyed to man through squirrel bites, as in the case of a child in Los Angeles studied by Stimson. Squirrels make good food for man but since the danger has been realized the shooting or trapping of them for food purposes has been forbidden in California.

An outbreak of pneumonic plague in Oakland, California, during August and September, 1919, started with a man who went squirrel hunting in the Berkeley Hills on August 11 and 13, and took ill August 15. The outbreak involved 14 cases, 8 of whom died (Kellogg, 1920). Another localized epidemic of the same type, but more extensive, occurred in Los Angeles in November, 1924. In this episode it is believed that the squirrels gave the infection to rats which in turn passed the disease on to a man who started the pneumonic epidemic.

Plague in the squirrel may be recognized by the gross anatomical lesions in the lymphatic glands, the liver and lungs. Involvement of the lungs is common in the squirrel. Many cases are subacute or chronic. Smear preparations from squirrels dead of plague are frequently negative for plague-like bacilli. The diagnosis may, therefore, be made by subcutaneous inoculation which is surer than the cutaneous method, as the latter often fails on account of the comparatively few plague bacilli present in squirrel lesions.

Squirrels may be destroyed by various means. At the present time, thallium sulphate-poisoned grain is superseding former methods. Placing carbon disulphide in burrows either by means of spray or on cotton and then closing the opening is an

effective method. Shooting and the use of grain poisoned with strychnine, phosphorus, or cyanide of potassium have destroyed many squirrels in California. They are not successful. Natural enemies are the coyote, wolf, badger, skunk, mountain lion, cobra snake, and the red-tailed hawk.

**Plague in Man (Peste).** Plague is an infection primarily of rats and other rodents, secondarily of man; caused by *Pasteurella pestis* (*Bacillus pestis*), a hemorrhagic septicemic organism. When the hemorrhages occur in the skin they are called "plague spots," which gave the name "black death" to the disease in the middle ages. In addition to this specific definition, the term "plague" still has a general meaning. There is much confusion in the literature, because formerly all serious epidemics were called plagues and we still speak of them as plagues.

There are two chief forms: bubonic and pneumonic.

**BUBONIC PLAGUE.** Bubonic plague is the common type of the disease. It is characterized by fever, depression, great prostration, and painful, tender inflammatory enlargements of the lymph nodes (buboes). The glands of the groin are most commonly affected (54 per cent) due to flea bites of the legs; next those of the axilla, then the head; occasionally multiple. When suppuration takes place it is regarded as a favorable sign. There is a high leukocytosis. The period of incubation is usually five to seven days. In this type the plague bacillus is locked up and is not eliminated in the body excretions. Bubonic plague, therefore, is not directly contagious from man to man.

The seasonal prevalence of bubonic plague varies in different localities and under other factors. Epidemics tend to subside when the mean temperature reaches 85° or falls below 60° to 55° F. In other words, in a hot climate epidemics flourish in the late winter and spring, to subside in hot weather, while in cool climates they are generally most severe in summer and decline with the onset of cold weather. Robertson (1923) has shown that in countries with a mean midwinter temperature of 45° F or below, bubonic plague is occasional, accidental and distinctly limited. It is essentially a disease of the tropics and subtropics, flourishing best in moderately warm, dry weather. Unfavorable weather conditions, such as heavy rains that flood exterior harboring places of rats, and the return migration of rats to buildings with the end of the crop season cause an increase in human plague of a seasonal character. The geographic distribution and seasonal prevalence correspond closely to the number and activity of the chief flea transmitter of the disease, *Xenopsylla cheopis*. In some localities there are other species of fleas which affect the seasonal prevalence, but these fleas have not been spread throughout the world as *Xenopsylla cheopis*.

**PNEUMONIC PLAGUE.** Primary pneumonic plague resembles croupous pneumonia except that the sputum is more bloody and less tenacious. The causative bacterium, *P. pestis*, appears in enormous numbers in the sputum. Few recover, death usually occurring in two to four days. The period of incubation is short, one to three days. The disease is highly contagious and usually is transmitted by close association, droplet or contact infection.

A secondary pneumonia may develop during the course of an attack of the bubonic type. Primary pneumonia may assume alarming epidemic proportions. In Manchuria in 1910-11 (60,000 deaths). This epidemic took place in winter.

and was one of the most virulent epidemics of modern times, the case mortality being almost 100 per cent. Other extensive epidemics have occurred, notably in central China in 1917-18, 15,000 deaths, and a second outbreak in Manchuria in 1920-21 with 9,000 deaths. A limited outbreak, which started from an infected squirrel, was reported in California in 1919 and a somewhat larger epidemic in 1924. It is generally believed that plague contracted from animals other than the rat, such as the tarbagan and squirrel, is apt to develop the pneumonic rather than the bubonic form.

**SEPTICEMIC PLAGUE.** The septicemic form of the disease is due to an overwhelming infection of the blood with the plague organisms which kill before the buboes have time to appear. Hemorrhages are common.

**PESTIS MINOR.** Pestis minor, or ambulant plague, is a mild form of the disease with fever and buboes which may suppurate, but with symptoms so slight that the patient does not go to bed.

**OTHER FORMS.** An intestinal form of plague occasionally occurs, causing diarrhea and the features of typhoid fever. In another type, skin lesions appear as vesicles and then pustules which might be mistaken for smallpox. Plague bacilli are present in the lesions. There is also a tonsillar type due to killing infected fleas with the teeth.

**DIAGNOSIS.** The diagnosis is made from the clinical symptoms, by finding the bipolar bacilli in material aspirated from the buboes; or in smears of the sputum in the pneumonic type. Some cases require guinea pig tests for diagnosis. In plague cases every illness associated with enlarged glands and all cases of pneumonia demand critical examination to avoid mistakes.

**HISTORY.** A comprehensive account of the history of plague has recently been published by L. Fabian Hirst (1953). The Philistines made offerings of golden images of the mice that marred the land and of their emerods to stay a pestilence. The epidemiology of this outbreak, which started on the seacoast at Ashdod and moved inland, smiting at Beth-shemesh 50,070, is clearly described in I Samuel, 4. The plague of Athens and the pestilence in the reign of Marcus Aurelius, according to Payne, may not have been this disease. Epidemics of varying severity occurred in Europe for over 1,100 years, from the sixth century in the days of Justinian to the middle of the seventeenth century. The most devastating was the "black death" of the fourteenth century which overran Europe and destroyed one-fourth of the population. The disease gradually subsided and disappeared from Europe but continued to be endemic in a few remote parts of the world. Suddenly, in 1894, it reappeared in Hong Kong and from there again spread over the world. This recrudescence of the disease thought to be geographically limited is one of the most striking facts in its epidemiology.

In 1664-65, the black death in London carried off 70,000 of a population then numbering 500,000. A graphic though imaginative description is given by Defoe in *Journal of the Plague Year*. Numerous references to the disease will be found in Pepys's *Diary*. Benvenuto Cellini describes his own case in his autobiography. The disease profoundly affected the economic, social and political history of Europe. Plague started in Stratford-on-Avon in July, 1564, when Shakespeare was a baby three months old. From July to December of that year, 237 deaths are recorded in

the parish register of the little vicarage of Avon. The infection swept away entire families.

**THE RECENT PANDEMIC.** The recent pandemic is the most widespread of having been carried to the four quarters of the globe by trade and travel. It is supposed to have originated in China in the Province of Yunnan on the Tibetan border, reaching Canton in 1894 and Calcutta and Bombay in 1896. In India, millions were swept away, the peak of mortality being reached in the four-year period from 1897 to 1908, when 4,325,237 deaths were attributed to this cause. In the succeeding years, the mortality rate in India gradually decreased to a low point in 1942, when there were 10,577 deaths. There was an increase during World War II to 41,700, with an abrupt fall in 1948 to 9,757 deaths attributed to plague. During this pandemic, plague spread to Singapore, the Philippine Islands, Arabia, Persia, Turkey, Egypt, West Africa, and later to Russia, parts of Europe, to the coast of North and South America, Central America, the West Indies, Mexico, and thence to the North American gulf coast. Nearly every country in the world was affected.

**ENDEMIC FOCI.** There are historic endemic foci where plague has slumbered for ages. Recently others have been disclosed. In central Asia on the eastern slopes of the Himalayas, and in northern China plague has been present for ages among the *tarbagans*. At present the most active endemic foci are in India and Burma. Plague is also endemic in other remote parts of Asia as well as on some of the near islands of which Ceylon, Java, and Madagascar have the greater commercial importance. In 1898, Koch discovered an endemic focus in Africa near the source of the White Nile in Uganda. Since then, foci have been discovered among wild rodents in South Africa, in the Mediterranean littoral of North Africa and in the Atlantic littoral of West Africa. In South America, there are endemic foci in Argentina, along the Atlantic Coast of Brazil, the Caribbean Coast of South America, in Peru, and Ecuador. Endemic foci entirely rural in character have been established on the islands of Maui and Hawaii in the Territory of Hawaii. More than 70 species of wild rodents have been found to be naturally infected.

In the United States, bubonic plague was first recognized in San Francisco in 1900. Up to February, 1904, when the city was declared free of plague, 121 cases with 113 deaths, principally in Chinese and Japanese confined to the Chinese quarters of the city, were officially acknowledged and reported. No further cases occurred with proven exposure within the city until May, 1907, a year after the great fire. The disease was widespread throughout the city, almost all cases being among white persons. Between May, 1907, and November, 1908, 159 cases with 77 deaths were reported. The discovery of plague in ground squirrels (sylvatic plague) followed, and since 1908 human plague has occurred principally as sporadic cases scattered through the western states and traced to contact with wild rodents.

In 1914, bubonic plague appeared in New Orleans. There were 30 cases and 15 deaths. In 1919, there were 12 cases in that city and in 1920, seven. In the latter year, the disease spread to adjacent communities and the Gulf States causing 11 cases in Texas and 10 in Florida. Since that time there have been no further cases of human plague traced to commensal rats in the United States.

**SYLVATIC OR CAMPESTRAL PLAGUE IN THE WESTERN U. S.** Annually, in widely separated sections of the western part of the United States, two or three species

cases of bubonic plague make their appearance. These human cases serve as indicators or signal posts of existing wild rodent enzootics or epizootics. In connection with these recurrences the operations of crews have gradually been extended to a wider and wider territory. Plague has been found by inoculation of pooled tissues from wild rodents or pools of fleas collected from them, into guinea pigs. These studies have demonstrated that infection is widely distributed among 13 western states (Meyer, 1942). The area now involved extends as far east as Kansas, New Mexico, Oklahoma, and Texas.

Until 1935, attention was largely restricted to the ground squirrel. During recent years, however, a great variety of animals has been investigated and infection has been found in 38 wild rodents, including not only 15 species of ground squirrels but kangaroo rats, marmots, meadow mice, wood rats, grasshopper mice, cotton tail rabbits and prairie dogs. Infected fleas have been taken from chipmunks, weasels, deer mice, harvest mice, cotton rats, and badgers.

The conditions which in the past have produced, and now maintain, these pockets of sylvatic disease are not clearly understood. They involve the ecology of the wild rodent and flea populations, the host relationships of *Pasteurella pestis*, and environmental factors. The theory that the infection originated with importation of rat plague into San Francisco by ships from the Orient at the turn of the century, and has gradually extended into the wild rodents of the western part of the United States has its supporters, while Meyer has maintained that sylvatic plague is far older than rat plague and it was probably enzootic on the American continent before its discovery in the west coast ports.

*Pasteurella pestis* (*Bacillus pestis*), discovered by Yersin during the Hong Kong epidemic of 1894, has more than fulfilled Koch's laws. Several accidents in which pure cultures have been introduced into man, producing all the symptoms and lesions of the disease, have added to the proof that this organism is the cause of plague. The bacillus is comparatively easy to isolate, grows readily on artificial culture media, and has characteristics that clearly distinguish it from all other species. In smears it usually appears as a short rod with rounded ends which show bipolar staining. There is a tendency to polymorphism, sometimes to the extent of round or coccoid forms. It is nonmotile, is decolorized by Gram's stain and grows well at room temperature.

Recognition of the bacillus rests upon the following characteristics: (1) Curious evolution forms upon salt agar within 24 hours; (2) stalactite growth in liquid media; (3) characteristic lesions produced by experimental plague in guinea pigs, rabbits, rats, etc. Kolle's method consists in rubbing the material containing the plague bacillus upon a shaved area of the skin of a guinea pig. The plague bacilli penetrate the skin, leaving other organisms behind. The skin of the guinea pig thus acts as a differential filter. (4) Finally, its pathogenicity may be neutralized by the use of antiplague serum.

*Pasteurella pestis* has no spore; its resistance corresponds about to that of the colon bacillus. It is readily killed by drying, sunlight, heat, and the usual germicides. In the feces of dead rats it may live for two months, in sputum from pneumonic cases 10 days, and under special circumstances from 6 to 15 days on fabrics and surfaces. There is, however, comparatively little danger of contracting the disease through fomites in real life.

**IMMUNITY.** One attack of plague usually protects for life. Occasionally, second attacks are noted in the same person, but they usually are mild. Artificial immunity of either an active or passive nature may be acquired by various procedures. The passive immunity induced by Yersin antiplague serum lasts only three weeks. *Yersin's serum* is obtained by immunizing horses with dead, then living culture. It has some therapeutic value when given early in the disease and a feeble, transient protective action. The active immunity produced by vaccination may last several months or longer. In India, plague workers are generally vaccinated once a year.

Vaccines may be prepared in several ways; even attenuated living cultures have been tried. The most widely used vaccine is *Haffkine's prophylactic* which is now prepared by growing the organisms for four weeks in bouillon at 25° to 30° C and then killing them at 55° C for 15 minutes. One half of 1 per cent of phenol is added. Two ml. of this vaccine is injected subcutaneously and in 10 days a second dose is given; sometimes after a week or more a third dose is injected.

From 1934 to 1941, Otten in the Dutch Indies, Pirie and Grasset in Johannesburg and Girard and Robic in Madagascar published observations based on the extensive use of vaccines made from living, avirulent cultures and interpreted the evidence as establishing the superiority of such preparations over dead cultures of *P. pestis* in protective value. However, an immunization procedure which gives a high degree of protection in experimental animals has been found to afford only a relative immunity for a short period of time in man. Some persons who were repeatedly vaccinated died of plague. Moreover, the reactions which follow vaccination with plague culture, whether alive or dead, are sometimes severe. The symptoms consist of a rise in temperature to 39° C, malaise, depression, and headache and swelling and pain at the site of the inoculation. The symptoms usually pass away in 24 to 48 hours. The recent studies of Meyer (1947) indicate that antigenic fractions of *P. pestis* can be prepared which when administered in serial doses induce a high level of antibody response in man with relatively mild local and systemic reactions.

**Plague Control.** The preventive measures necessary in controlling the two types of human plague are fundamentally different; thus, the primary pneumonic form or cases of secondary plague pneumonia demand strict isolation, as this form is one of the most highly contagious infections on the list. Doctors, nurses, ward tenders and others in close contact with cases run a special hazard. Bubonic plague is not directly communicable from man to man. Its control depends upon the eradication of the disease from among infected rodents. Human bubonic cases should be isolated in hospital wards, although contact infection is unlikely when ordinary care is used in handling such cases.

The sulfonamides have been shown to have curative effects in the treatment of plague. The antibiotics, chloramphenicol, aureomycin and streptomycin are effective against experimental bubonic or pneumonic infections in monkeys when therapy is instituted during the early phases of the disease (McCrumb and others, 1950). Contacts and suspected contacts of patients with pneumonic plague are first detected and segregated; temperatures are taken and chemoprophylaxis instituted. From three to eight grams of sulfadiazine should be administered each day for

seven days. The extent to which plague vaccine is to be employed on exposed contacts and on the general population must be decided locally.

In any community where plague first appears a general warning should be issued immediately regarding the danger of contact with sick and dying rodents and their fleas and the part played by them in the spread of the disease.

An active antiplague campaign demands a central head, under whose direction could be organized laboratory facilities for diagnosing plague in man and rodents; facilities for the detection of human cases; a department thoroughly versed in methods of suppressing rat and flea populations. Trapping rats is required not only for their destruction but also to determine the extent of the disease among them and location of infected foci. In order to reduce the rodent population to the point where plague will disappear it will be necessary actively to employ all the measures discussed under the heading of rodent control (see Section 1, Chapter 8).

Buildings in which there are human cases of plague and where infected rodents are discovered, and other structures and surroundings in the same locality demand immediate intensive treatment to kill rats and infected fleas in order to prevent secondary cases and to abolish an infected rodent focus.

The results of antiplague measures vary greatly in different parts of the world. In some cities the disease has been quickly conquered, while in others progress has been slow, and in some places there has been complete failure in eradicating rodent infection. A number of factors have influenced the results obtained by eradication measures.

1. The degree of rodent infestation with *Xenopsylla cheopis* has a decided influence on the rapidity with which plague spreads and the extent of rodent infection. The degree of flea infestation is largely determined by climatic conditions: rats living out of doors where there is excessive rainfall are relatively free of fleas compared to those in drier zones.

2. Suppressive measures should give quicker results in highly susceptible, urban communities where plague has existed for some time and the rodent population is more or less immune at the beginning of the epidemic.

3. The extent of rat infestation of a community, the type of building construction, and the sanitary education of the inhabitants have a decided bearing on the prevalence of plague and the difficulty of eradication. Ratproof construction tends to limit the degree of infection and renders active suppressive measures more certain.

4. The presence of plague among field rodents is a continual menace to nearby urban communities and complicates the eradication of the disease because of the great difficulty in controlling the far flung and wild endemic focus.

5. The presence of an active flea transmitter other than *Xenopsylla cheopis* makes eradication more difficult. *Xenopsylla hawaiiensis* found on field rats in the rural plague infected zones of the Hawaiian Islands is a flea of this class.

In the attempt to control plague in urban communities in the past, emphasis has been placed principally on suppression of the rat population. Obviously, a more rapid and direct approach is the suppression of the flea population. With the introduction of the use of DDT during World War II, this approach became practical. It was first used extensively by the United States military authorities in a control of plague at Dakar in 1944. The control methods used in this outbreak have been fully described by Gordon and Knies (1947). According to these authors, the modern

control of plague is based on the premise that the flea is the primary objective and that rats suffering from the disease or harboring fleas are of secondary importance. The principle of focal disinfection applies. The attack on the flea population should center about known infested areas, the house or building where a plague patient has been discovered. Having circumscribed an area within a radius of about 200 yards around the infected house, all persons and infestable things within that area should be disinfested, starting peripherally, working toward the central focus of infection. This is accomplished in respect to persons by dusting every individual in the area with a 10 per cent DDT powder. Pets and domestic animals are treated in the same way. Clothing, bedding, and furniture within the house are likewise dusted with DDT powder. Walls, ceilings and floors of houses, with especial attention to cracks, are treated with DDT residual sprays and oils. Rat harborages and runways are dusted with DDT insecticide powder. Rat-trapping lines are run radially beyond the focal zone. As plague-infected rats or new cases are detected, flea disinfection is extended, proceeding inward from the outermost point of suspected infection. In this manner, the area of focal disinfection is enlarged by extension to a general community basis. With the employment of such measures, it is anticipated that in the future plague will be more promptly and effectively controlled in an urban area.

*Personal prophylaxis* for those who must live in and visit infected regions consists in living and working in rat-free buildings. Haffkine's prophylactic vaccine is recommended for doctors, nurses, and others treating pneumonic cases. Other measures are evident from the context.

**MARITIME QUARANTINE.** Plague has been carried from one seaport to another by the transporting of infected rats on board vessels. Maritime quarantine, therefore, finds its greatest justification in keeping out plague. The universal adoption of measures for rat-proof construction of vessels and periodic rat infestation inspection with fumigation when necessary will greatly lessen the menace of plague introduction into clean ports. The measures used to prevent the ingress and egress of rats on infected and clean ports is discussed under the heading of the suppression of rats on vessels. The period of detention of personnel for a plague ship is seven days. It is comparatively easy to keep plague out of a seaport. Once in, it may require a long time, much ingenuity and considerable outlay to root out the infection.

TULAREMIA

Tularemia is an infectious disease caused by *Bacterium tularense* [Synonym: *Streptococcus tularensis* (Bergey and others)]. Primarily, it is a fatal bacteremia of rodents, especially rabbits and hares; secondarily, an accidental infection of man. Tularemia is remarkable in that it occurs among a wide and extraordinary range of wild animals and is contracted by every known method of transmission: usually through wounds or insect bites; sometimes through the conjunctiva or the broken skin, and even by ingestion.

Table 6-3. Cases of tularemia reported in the United States

Year	Cases	Deaths

\* Case fatality 4.9 per cent.

**History and Synonyms.** McCoy first described the disease in 1911 as a "plague-like disease of rodents" in California, Tulare County; hence the name tularense. McCoy and Chapin in 1912 discovered the causative organism, *Bacterium tularense*. Martin, an ophthalmologist of Arizona, called attention in 1907 by correspondence to five human cases occurring in his practice caused by skinning jack rabbits. Pearce of Utah, in 1911, described six human cases under the heading of "insect bites." Gil, Wherry, and Lamb of Cincinnati, in 1914, described a human case as "*Bacillus tularense* infection of the eye." Francis, in 1919 and 1920, described "deer fly fever" of Utah, recognized its identity with McCoy's "plague-like disease of rodents" and named the disease "tularemia."

**Geographic Distribution.** Human cases have been reported from 48 states of the United States and from the District of Columbia. During the 22 years from 1924 to 1945, before the discovery of streptomycin, the number of cases of tularemia reported by state health officers to the U. S. Public Health Service was 19,208 and the number of deaths recorded by the U. S. Office of Vital Statistics was 1,432, giving a mortality of 7.4 per cent which included all types of tularemia. The disease has been reported in Japan in 1925, in Russia in 1928, in Norway in 1929, in Canada in 1930, and in Sweden in 1931. With increasing knowledge the area is widening.

**Zoologic Distribution in Nature.** *Bacterium tularense* has been isolated from naturally infected animals as follows: wild rabbits and hares and their ticks, widespread in the United States; California ground squirrels, often; ground squirrels of Utah, wild rats of Los Angeles, wild mice of California, quail, ruffed grouse, sharp-shinned grouse, and gray foxes of Minnesota, once each; sage hens and their ticks in Montana, once; sheep of Idaho, three times; wild rabbits of Japan, Norway, and

Canada; the water rat of Europe (Russia); wood ticks of Montana and Minnesota, often; and wood ticks of California, once.

**Transmission among Wild Animals.** Bloodsucking insects (ticks, lice, flies, and perhaps fleas) are believed to transmit the infection from animal to animal in nature. Domestic rabbits are just as susceptible as wild rabbits but have never been found naturally infected, probably on account of the lack of transmitting insects.

**Susceptibility.** It is noteworthy that domestic animals are largely resistant. Many rodents are susceptible. Various degrees of susceptibility are noted: highly susceptible (man, monkey, ground squirrel, rabbit, guinea pig, mouse, groundhog, muskrat, beaver, ferret, weasel, cotton rat, water rat of Europe, prairie dog, chipmunk, pocket gopher, and porcupine); slightly susceptible (cat, sheep, goat, white rat, wild rat (*norvegicus*), coyote, opossum, quail, Hungarian partridge, sage hen, ruffed grouse, sharp-tailed grouse, wild fox, and mallard duck); not susceptible (horse, cattle, hog, dog, chicken, pigeon, turkey, ringnecked pheasant, hawk, badger, and skunk).

**Clinical Types.** There are four clinical types of the disease: (1) *ulceroglandular type*, in which the primary lesion is a papule of the skin, later an ulcer, accompanied by enlargement of the regional lymph glands. Subcutaneous nodules appear between ulcer and regional lymph nodes. In the pulmonary form there is pleurisy with effusion. There is also a meningeal form. (2) In the *oculoglandular type* the primary lesion is a conjunctivitis accompanied by enlargement of the regional lymph glands. (3) In the *glandular type* there is no primary lesion at the site of infection, but there is enlargement of the regional lymph glands. (4) In the *typhoid type* there is no primary lesion, nor is there glandular enlargement. (The word "typhoid" is used here in the sense of an absence of manifest external lesions and not as signifying the so-called typhoid state of mind.)

**Sources of Human Infection.** A large number of cases of tularemia have been studied with reference to type and source of infection.

1. *Ulceroglandular type*, 1,328 cases: *fly bite* (*Chrysops discalis*), 34 cases in Utah, Montana, Wyoming, Idaho, Oregon, Colorado and Nevada; *tick bite* (*Dermacentor andersoni*), 37 cases in Montana, Wyoming, Idaho, North Dakota, South Dakota, Nevada and California; *tick bite* (*Dermacentor variabilis*), 58 cases in Arkansas, Texas, Louisiana, Missouri, Kansas, Illinois, Tennessee, Georgia, North Carolina, Virginia and Minnesota; *insect bite* (species ?), 9 cases in California, Colorado, Nevada, Michigan, Louisiana and Texas; *sheep contact* and consequent contact with wood ticks and their feces as in shearing, herding and butchering, 7 cases in Montana, Wyoming, Nevada and Idaho; *wild rabbits* shot and dressed, 163 cases; bought or sold in markets, 169 cases; dressed or skinned or cut up for dog feed, hog feed, chicken feed, fox feed, fish bait or trap bait, 807 cases; *water rats* of Europe (*Arvicola amphibius*), killed and skinned for their pelts in Russia, about 1,000 cases; occasional cases from skinning and dressing tree squirrels, quail, sage hens, opossums, deer, ground-hogs, muskrats, skunks, coyotes, a wild fox, hog, a bull snake; an occasional case from bite or scratch of dogs, cats, skunks, coyotes, tree squirrels, Montana ground-squirrels, opossums, dog, hog, lamb or white rat, contamination of mouth parts or paws being assumed. The list is impressive.

2. *Oculoglandular type*, 64 cases: *wild rabbits* skinned or dressed, 40 cases; a fly crushed between the fingers, 1 case; ticks pulled from a horse, cow or dog 4

shed between the fingers, 10 cases; *rabbit blood* or bloody water spurted into the eye, 2 cases; *bile* from a ruptured gallbladder of a ground-hog spurted into the eye, 1 case.

3. *Glandular type*, 29 cases: *wild rabbits* dressed, 24 cases; *tick bite*, 1 case; *ingestion* of insufficiently cooked wild rabbit, 3 cases; *experimental human infection* on back of hand, 1 case.

4. *Typhoid type*, 55 cases: *laboratory workers* who autopsied infected guinea pigs, rabbits, or white mice or handled infected living ticks, 37 cases; *wild rabbits* dressed, 10 cases; *tick bite*, 4 cases; ingestion of insufficiently cooked wild rabbit, 1 case; an *opossum* skinned, 1 case.

**Symptoms.** The incubation period is from 1 to 10 days, the average being about three and one-half days. The onset is sudden with headache, chills, body aches, vomiting and fever. The primary lesion, whether on the skin or in the conjunctival sac, usually proceeds to ulceration and quickly gives rise to inflammation of the regional lymph nodes which suppurate in about half of the cases.

The fever lasts two or three weeks and may reach 104° F with a transient remission on the third or fourth day, or daily remissions suggesting a septic type of fever. Convalescence is slow and drags along with weakness for several months, sometimes longer. Some cases are ambulant throughout. Skin eruption and subcutaneous nodules are noted in some cases. Recovery usually occurs without sequelae. Pleural effusion is not rare. Symptoms suggesting pneumonia constitute a grave prognostic sign. Death occurs in about 5 per cent of cases.

**Diagnosis.** The history of the case and the symptoms may suggest tularemia but diagnosis depends upon agglutinins or cultures of *Bacterium tularense*. Specific agglutinins appear in the blood at some time in the second week and remain for a long time—even several years. Material from the site of infection or from the enlarged glands inoculated into guinea pigs causes their death within a week with enlargement of the regional lymph glands and small areas of focal necrosis studded in the liver and spleen from which *Bacterium tularense* can be recovered in pure culture on coagulated egg yolk or blood-dextrose-cystine agar. Cross agglutination with *Brucella abortus* by the blood serum is rather common and may rarely necessitate a precipitin absorption test if *abortus* and *tularense* are agglutinated out to the same solution of serum.

*Bacterium tularense* is a small organism occurring regularly in coccoidal and bacillary forms and very rarely bipolar; it is Gram negative, aerobic, without spores, nonmotile; it grows on coagulated egg yolk or blood-dextrose-cystine agar, but not on plain agar. In smears, it stains well with crystal violet and in sections it stains with Giemsa solution. In three of eight attempts it passed through Berkefeld filters which held back a small staphylococcus.

The organism is killed at 56° to 58° C in 10 minutes. Formaldehyde solution, alcohol and the usual germicides are effective. In bedbug feces the virus resisted boiling for 25 days.

**Cultures** on blood-dextrose-cystine agar, kept at room temperature, require monthly transfer and quickly lose virulence, but cultures kept between 12° C and 15° C and transferred every two months retain their virulence about five years. Annual transfer of cultures is sufficient to keep them viable and virulent.

*Refrigerated carcasses* of infected rabbits stored at 3° C showed survival of

virulent organisms in spleen for one month, in muscle of thigh four months, in brain four months and in spinal cord five months. Carcasses stored continuously without thawing at  $-15^{\circ}\text{C}$  showed survival of virulent tularensis organisms in bone marrow of femur 10 months, in liver 11 months, in muscle of thigh 12 months, in spleen 19 months, and in brain and spinal cord two years.

**FREEZING AND THAWING.** Rabbit livers and spleens which were stored frozen at  $-15^{\circ}\text{C}$  during each night but allowed to thaw at  $20^{\circ}\text{C}$  during each intervening day were free from virulent infection at the end of seven days of such alternate freezing and thawing.

*Glycerinated spleens* of infected guinea pigs (spleens placed entire in pure undiluted neutral glycerin) showed survival of virulent organisms for one month at room temperature, six months at  $12^{\circ}\text{C}$ , two years at  $3^{\circ}\text{C}$  and six and a half years at  $-15^{\circ}\text{C}$ . The naked bacilli suspended in pure glycerin and stored at  $-15^{\circ}\text{C}$  were virulent for two years and nine months.

**Modes of Transmission.** **INSECT TRANSMISSION.** Transmission from rabbit to rabbit in nature is by the rabbit tick *Haemaphysalis leporis-palustris* Packard, the rabbit louse *Haemodipsus ventricosus*, the wood tick *Dermacentor andersoni* and the dog tick *Dermacentor variabilis*, which keep the infection alive in rabbits throughout the year.

Insect transmission to man is (1) by the wood tick *Dermacentor andersoni* Stiles; (2) by the dog tick *Dermacentor variabilis*; and (3) by the bloodsucking fly *Chrysops discalis* (deer fly).

**TICK INFECTIONS.** *Dermacentor andersoni* is commonly found in Montana and the surrounding states. It feeds on rabbits, domestic animals, and man, and is active during March, April, May, and June. When feeding, it attaches beneath the clothing or in the hair, remaining attached for days, during which time infection takes place by the introduction of its feces into the biting wound. This tick harbors the infection in its coelomic fluid, in the epithelial cells of its rectal sac and gut and in its feces. The virus is capable not only of surviving the winter in this tick and of being transmitted from stage to stage as the tick develops, but it is transmitted through the egg to the next generation of ticks. The mere handling of a tick may cause infection. *Dermacentor variabilis* is found commonly in the southern states. It feeds on rabbits, dogs, and man, and has caused cases in all months of the year except November, December, and January. It attaches beneath the clothing or in the hair.

**FLY INFECTIONS.** The horsefly *Chrysops discalis* is commonly found on horses and cows in Utah and the adjoining states during the months of May, June, and July. This fly, after biting an infected rabbit, bites man on an exposed part of the body—face, ears, or neck. In contrast to the tick, the fly remains infected not over 14 days and it feeds several times a day but only for a few minutes at a time. Transmission is purely mechanical, due to contamination of its mouth parts.

**CUTANEOUS WOUND INFECTIONS.** In the majority of human cases a wound entry has been inflicted at the site of cutaneous infection either at the time of infection or shortly before or after. These wounds consist of cuts, punctures or scratches by fragments of shot-shattered rabbit bone or by knife, nail, barbed wire, thorn, briar or burr or splinter of wood, etc. In the fly-bitten, tick-bitten and animal bite cases the bite constitutes the wound. Cutaneous inoculation, *i.e.*, rubbing infectious material on the abraded skin of the abdomen of a guinea pig, is the routine method.

propagation of a strain of tularemia in the laboratory. This method also serves to "sterilize" a pure culture from grossly contaminated tissue.

**PENETRATION OF UNBROKEN SKIN.** Evidence that *Bacterium tularense* can penetrate the normal skin is as follows: (1) Ohara gently rubbed the back of a hand with the heart and blood of a wild rabbit found dead, thus causing a typical case of tularemia confirmed by the agglutination test and by characteristic cellular pathology in the regional lymph nodes of the axilla but there was not any lesion on the hand. (2) Laboratory infection of 37 workers did not cause any lesions of the hands nor lymph node enlargements. One of these had derived his infection through a prick of his finger with a thumb tack which held an infected guinea pig on the board. (3) Dressing of wild rabbits in 24 cases resulted in absence of lesion on the hands with enlargement of regional lymph nodes. (4) Rabbits and guinea pigs become infected regularly in the laboratory by the gentle application of a culture to their normal skin between the shoulders but without abrading, rubbing, shaving or clipping. In the last analysis, no one really knows at the present moment whether he has a small abrasion of the skin of his hands, much less does he know what the condition was three or four days ago.

**LABORATORY INFECTIONS.** In 11 laboratories the disease has been contracted by 17 workers, who had either (1) performed or assisted at necropsies of infected guinea pigs, rabbits or white mice, or (2) had held infected living rabbits or guinea pigs, or (3) had handled infected living ticks. In these cases the infection enters through the skin of the hands, presumably the unbroken skin.

**MARKET INFECTIONS.** During the months of November, December and January which embrace the "open season" for wild rabbits these rodents are shot, shipped long distances, and offered for sale in the markets in large numbers. Of a total of 100 rabbit livers examined in the Washington, D. C., market, nine, or slightly more than 1 per cent, were found to contain virulent *Bacterium tularense*. Twenty-two human cases of tularemia were traced to rabbits sold in that market and dressed by market men, cooks or housewives. A serological examination for antitularense agglutinins in the rabbit dressers in the market should furnish a quick and reliable answer as to the prevalence of tularemia in rabbits.

**EYE INFECTIONS.** The conjunctiva is more susceptible than the skin as shown by 53 cases having the primary seat of infection in the conjunctival sac without evidence of a simultaneous lesion on the hands which conveyed the infection to the eyes.

**INGESTION.** Insufficiently cooked rabbit meat caused three serious outbreaks. The marrow of infected rabbits is known to be studded with lesions rich in organisms, which, in conjunction with red juice around the bones and mass ingestion of meat, results in fulminating infection of man which may terminate fatally in only a few days. Laboratory animals are very susceptible to infection by ingestion of food which has been artificially contaminated with infected animal tissue. White mice regularly become infected after eating infected bedbugs. Mice become infected by eating infected mice.

In 1935 an explosive water-borne epidemic of tularemia in the U.S.S.R., was reported by Karpoff and Antonoff. Over 43 cases were observed in a group of farm workers who used water from one stream which was found to be contaminated with *Bacterium tularense*. The portal of entry of infection appeared to be the tonsils and buccal

mucosa and in some instances the conjunctiva (Karpoff and Antonoff, 1936). In the United States since 1942, contamination of numerous streams in Montana at one time or another, often persisting for months, has been repeatedly demonstrated at the Rocky Mountain spotted fever laboratory (Jellison and others, 1942; Parke and others, 1943). In most instances the presence of the organism in water has been associated with tularemia in beavers and muskrats inhabiting the streams or ponds concerned. Many cases of tularemia were contracted by persons who skinned or handled such diseased animals, but up to 1950 there was little evidence of human infection resulting from direct contact with contaminated water. In that year, Jellison and others (1950) reported the occurrence of four cases of tularemia associated with one domestic water supply under circumstances which appeared to exclude other likely sources of infection. *B. tularensis* was recovered from samples of the suspected domestic water supply upon two occasions. Four of the individuals who consumed water from this particular supply experienced a typical clinical illness with tularemia, with the primary infection in the tonsils and buccal mucosa.

**NASAL SECRETIONS, URINE AND FECES.** Rabbit urine, rabbit nasal secretions and mouse urine cause tularemia by subcutaneous injections, but not by feeding. Tick feces and bedbug feces are very infectious by inoculation into guinea pigs.

**COMMERCIAL DEMAND FOR PELTS.** Water rats of Russia were an unsuspected host of tularemia until the commercial demand for their pelts suddenly opened the avenue of infection, resulting immediately in about 1,000 cases. No human case of the disease has ever been traced to the California ground squirrel which was its first recognized host, but such cases may be only awaiting a commercial demand for those squirrel skins. Furriers, tanners, and jobbers in rabbit skins have not become infected owing to the lack of contact of their hands with the raw flesh and blood of wild rabbits.

**Immunity.** One attack confers permanent immunity in man, there being no record of a second attack. The highly susceptible laboratory animals (guinea pigs, rabbits, and white mice) practically all die when exposed to cultures of maximum virulence, the only exception being the rare rabbit which survives the injection of a series of cultures of increasing virulence.

**Prevention.** Although the disease is preventable, the number of reported cases in the United States is showing a slight yearly increase. Measures for personal protection are at the command of everyone. *Rubber gloves* furnish complete protection to the hunter, marketman, cook, housewife, laboratory worker and to the trapper and skinner of game. *Mental alertness* to the danger will help in avoiding the bite of insects and will forestall the deliberate handling or squashing of bloodsucking ticks, flies or their feces. *Disinfection* of bites, cuts, punctures, and scratches should be practiced, but the measure has often failed especially where the puncture was made by a sharp spicule of shot-shattered, marrow-smeared rabbit bone. *Disinfection* of ulcers, abscesses, sputum, conjunctival secretion, urine, and feces would be suggested but no case has been traced to those sources. *Thorough cooking* of wild game, especially rabbits and hares, not allowing any red juice to remain about the bones, is essential. *Immunes* should be employed for all work involving contact with the animal and insect hosts of the disease. A warning to the poor sportsman is necessary: he should not shoot the rabbit which is on the point of his gun, nor take a rabbit found dead, nor one which a cat or dog has brought in, nor the one which

oy has killed with a club. *Refrigeration* of wild rabbits with a view to rendering n safe by prolonged cold storage is economically unprofitable because of the g life (two years) of the organism in their tissues at  $-15^{\circ}\text{C}$ . *Isolation*, quaran- and house disinfection are not indicated. *Market inspection* of wild rabbits is racticable because the spotted spleens and livers have usually been discarded in ssing before arrival at market and because infected rabbits may be shot and keted before the small lesions, though present, attain macroscopic size. *Repeal* ne game laws which protect rabbits, and discontinuance of the practice of restock- the rabbit population would result in their immediate extermination from the ly agricultural states, but jack rabbits would still remain a pest west of the sissippi River.

Since the discovery of streptomycin by Waksman and the publication by Heilman others of its bactericidal effects on tularemia in laboratory animals, cases of remia in man treated by that antibiotic have been reported in the literature shay, 1947). Reviewing this evidence Francis (1947) concludes that this anti- ic is remarkably effective in bringing about prompt clinical recovery and in ncing the survival of *B. tularensis* in the human body from a prospective long term ve months' duration to a five-day period. There is evidence also that aureomycin hloramphenicol (chloromycetin) are effective in the treatment of the human ase (Parker and others, 1950).

The development of a vaccine which would be satisfactory in prophylaxis has ived considerable attention from investigators in recent years. A method which ld afford a high degree of protection without undesirable local and constitutional tions has yet to be devised. Recent reports, however, are encouraging (Kadull others, 1950).

#### RELAPSING FEVER

LLOYD E. ROZEBOOM, Sc.D.

Relapsing fever comprises a group of specific infections caused by spirochetes e blood, characterized by relapsing attacks of fever lasting about a week and rring at like intervals. These spirochetes are placed in a genus designated as *Borrelia* or *Borrelia*, and the several species differ from one another in their

staining reactions, pathogenicity, and transmissibility by the species of ticks and lice which serve as vectors. A number of species have been described from various soft ticks and animal hosts; some of those which infect man are *B. duttoni* from Africa, *B. persica* from the Middle East, *B. berbera* from North Africa, *B. venezuelensis* from the neotropical region, and *B. turicatae* and *B. hermsi* from North America. The epidemic, louse-borne relapsing fever is caused by *B. recurrentis*.

Clinically, the relapsing fevers resemble one another, except that some are more virulent than others. The disease is characterized by sudden onset, intense frontal headache, and pains in back and limbs. The fever continues from three to five days and falls by crisis. The temperature remains normal for about a week, when the fever repeats itself. There may be 4, 5 or even 10 such relapses. The spirochetes are found in the peripheral blood only during the febrile period.

Obermeier in 1868 discovered the "spirillum" of epidemic European relapsing fever in the blood. Carter and Koch in 1878 showed that the infection may be transferred to apes by the inoculation of the blood of a patient. Munch and Moczutkowski transferred the disease by the inoculation of relapsing fever blood to healthy individuals.

**Louse-borne.** Epidemiologically, the disease exists in two forms, louse-borne and tick-borne. The former occurs in epidemics, and is dependent upon conditions which permit the building up of louse populations to the point where these insects are capable of acting as vectors of the spirochetes directly from man to man. It thus may co-exist with epidemic typhus. Such epidemics have occurred principally in Europe, Asia, and India; they occurred in New York and Philadelphia in 1869, but this type of the disease no longer exists in the United States. After the louse has imbibed a meal of infected blood, the spirochetes penetrate the gut wall and enter the insect's haemocoel. Most of the organisms are killed in the gut of the louse, and as only a few successfully penetrate the gut wall, they can not be found in the blood or tissues of the louse until several days have elapsed. During this time they apparently multiply by transverse division; older ideas that they passed through a granular stage are no longer tenable. They become numerous enough to be demonstrable microscopically after about a week. The spirochetes in the haemocoel are in a blind alley; they can not be transmitted by the bite or feces of the insect. When the louse is crushed, the skin or mucous membranes of the host are contaminated with the spirochete-laden blood of the louse, and the organisms gain entrance into the body through the skin scarified by scratching, or through the intact mucous membrane or conjunctiva.

**Tick-borne.** Tick-borne relapsing fever depends upon the habits of the tick and the tick hosts for its transmission. Dutton and Todd and also Koch, in 1903, showed that in Africa the tick, *Ornithodoros moubata*, was capable of transmitting the spirochetes. In the tick the spirochetes penetrate the stomach wall and enter the haemocoel. From here they invade the various tissues, including the salivary glands, the coxal glands, the Malpighian tubules, and the ovaries. Transmission to the vertebrate host may thus be effected by the injection of salivary secretion during feeding, by the coxal fluid which is excreted by some ticks while feeding, and by contaminated feces. In the ovaries, the spirochetes penetrate the eggs and hence are transmitted hereditarily from mother to offspring. Hereditary transmission may continue for several

rations without the reinfection of the tick by feeding upon infected blood; the tick thus acts as a reservoir as well as a vector.

In Africa, *O. moubata* and *O. savignyi* live in and about human habitations. They thus are responsible for direct transmission of spirochetosis from man to man, and may maintain a high endemicity. Koch observed natural infection rates in *O. moubata* as high as 50 per cent. The African natives had associated relapsing fever with *O. moubata* long before the scientific proof of the role of the tick as a vector was obtained.

*O. tholozani* are distributed from the Mediterranean region to central Asia. They are found in animal burrows, caves, rock shelters, and the like, where they feed upon rodents. People invading such haunts may be bitten by these ticks and contract relapsing fever.

*O. erraticus* live in rodent burrows in Africa and the Middle East and may occasionally transmit relapsing fever to man.

In Central and South America, *O. rudis* live in houses and thus can transmit the parasites from man to man or from rodents to man. *O. talaje*, which are found in Kansas and California to Argentina, seldom, if ever, feed upon man but probably are important in maintaining a reservoir of infection among rodents. However, it is not known whether spirochetes from *O. talaje* are transmissible by *O. rudis*. In western North America, *O. turicata* are found in caves and animal burrows; sporadic cases of relapsing fever occur among persons who enter the tick's habitat. *B. hermsi* live in nests of various wild rodents in the Rocky Mountain region. Hunters living in mountain cabins may be bitten and infected by these ticks when they wander from nests built beneath or in the cabin. Another species in the Rocky Mountain area, *O. parkeri*, seldom feeds upon man, but it also lives in burrows and nests and hence may be of importance in maintaining a reservoir of infection among wild rodent hosts.

**Extrahuman Survival.** No animal reservoir has been found for the louse-borne relapsing fever, but some workers doubt that man can be the reservoir. Lice are not; there is no hereditary survival of the spirochetes in these insects; furthermore, as the spirochetes cannot leave the louse unless the insect is crushed, transmission to only one person is possible by a single louse. The possibility exists that there is an animal reservoir for *B. recurrentis*, with an associated tick vector, and that louse-borne epidemics may originate under favorable circumstances from sporadic infections in man caused by ticks. Final proof is still lacking. Baltazard and his associates present evidence indicating that passage of *B. recurrentis* through rodents causes a transformation toward the characteristics of the tick-borne spirochetes. However, attempts to transmit the tick-borne spirochetes through lice have not been especially successful; also, the tick-borne spirochetes usually show a high specificity for certain tick species. Heisch, who points out that the tick-borne *B. duttoni* of Africa is not transmitted by lice, states that it is a mystery why epidemics of louse-borne *B. duttoni* do not occur.

There are conflicting reports regarding the efficacy of the arsenicals in the treatment of the disease; these discrepancies may be reconciled in part by taking into account the differences between strains or species of spirochetes and the development of arsenic-resistant strains.

More recently satisfactory results have been reported following administration of penicillin.

Recent discussions on the treatment of relapsing fever are those of Bergeret and Raoult (1948); Davis (1948); and Magee (1942).

### THE TYPHUS GROUP

Typhus fever is undoubtedly one of the oldest pestilential diseases of mankind. Called by many names and confused with other fevers, it is not until the sixteenth-century writings that it can be certainly recognized as causing devastating epidemics. With plague, smallpox, typhoid and dysentery, it was a scourge of armies and civilian populations throughout the Middle Ages; it frequently played a decisive role in wars. The manner in which the course of the history of Europe was affected by these pestilences has been graphically portrayed by Zinsser in his "Rats, Lice and History," which every student of military medicine should read. The appellation "typhus" originated with Sauvages in 1760 and was derived from the Greek *typhos*, literally meaning smoke. Hippocrates used this word to describe a "confused state of the intellect; a tendency to stupor." Originally, typhus designated the self-limiting continued fevers which were characterized by stupor. In 1829, the French clinician, Louis, clearly differentiated typhus fever from typhoid fever. In the United States, attention was called to this differentiation in 1837 by W. W. Gerhard of Philadelphia, who had studied under Louis; and since then typhus fever has been recognized as a contagious disease characterized by sudden onset with high fever, severe headache, generalized maculopapular eruption, and termination by rapid lysis in about two weeks, or by a fatal issue.

About the turn of the century, there began to appear in the medical literature from various parts of the world descriptions of fevers which resembled typhus but differed from it in clinical course or mode of occurrence. These typhus-like fevers were gradually differentiated in their etiology, pathology and epidemiology. Classified according to their arthropod vector, the four principal diseases in the typhus group are: (1) louse-borne, or epidemic typhus; (2) flea-borne, or murine typhus; (3) tick-borne, particularly Rocky Mountain spotted fever; (4) mite-borne, or scrub typhus (tsutsugamushi disease).

Further investigations established the fact that these diseases were caused by micro-organisms intermediate in character between bacteria and viruses and called rickettsiae. They are small pleomorphic coccobacillary organisms which are visible

microscopic preparations with Giemsa or Macchiavello stain and which cannot be grown on artificial media. They multiply only in certain cells of susceptible arthropods and vertebrate hosts and of chick embryos. As their natural history has developed, it appears that they are primarily parasites of arthropods. The human diseases which they cause are sometimes designated "rickettsioses." These include not only the typhus-like fevers but also three other human diseases which have been differentiated; namely, trench fever, Q fever, and rickettsialpox.

### EPIDEMIC TYPHUS FEVER

(*Typhus Exanthematicus*, *Classic or European Typhus*)

Typhus fever is an acute specific infection caused by *Rickettsia prowazeki*. The period of incubation is from 6 to 15 days, commonly about 12 days. The onset is more or less sudden with chills, fever, and severe headache. Between the fourth and seventh days a maculopapular rash appears and becomes generally distributed over the body. At first the spots are erythematous in character disappearing on pressure, but after the second day become persistent and often converted into true chancres. There is an early and great prostration, with heavy flushed countenance and injected conjunctivae. Nervousness, mental dullness, and insomnia may be followed at the end of the first week by delirium. In the very severe cases this develops into stupor and coma. Duration of the fever is from 10 to 21 days, usually 14 days, terminated by rapid lysis. Convalescence may be characterized by weakness and depression. According to Murchison, the case fatality rate, based upon 18,268 admissions in London Fever Hospital, 1848 to 1870, was 19 per cent. The case fatality was about 3 to 4 per cent in childhood and rose steadily with advancing age, so that more than 50 per cent of the cases in old people terminated fatally. Today, with good medical care and early judicious administration of such antibiotics as streptomycin or aureomycin, the risk of a fatal issue can be greatly decreased.

The clinical manifestations are due to the ability of the rickettsiae to multiply within the endothelial cells lining the small blood vessels. Vascular lesions having a necrotic histologic appearance sometimes referred to as Fraenkel's nodules are not numerous in the skin, central nervous system, and myocardium, but are found scattered widely throughout the organs of the body.

**Laboratory Diagnosis.** The clinical course of the disease and the characteristics of the eruption are sufficiently distinctive to permit clinical diagnosis. Serological confirmation is sought through employment of the Weil-Felix test or the complement-fixation reaction.

The investigations of Weil and Felix in 1916 and of Felix (1944) and others, have established the fact that patients sick with typhus fever develop agglutinins for certain strains of *Proteus*, namely, X19 and X2. X19 has been found to be the most sensitive indicator and suspensions made from the nonmotile O variant the most specific. Agglutinins for OX19 and OX2 appear in the sera of most typhus patients between the fifth and eighth day of the illness. In more than 90 per cent of cases the titer for OX19 rises to 1:160 or higher, sometimes reaching a titer of 1:2,560 or more. Diagnostic significance is attached to a rise to 1:160 or greater. Rarely, individuals are encountered whose serum agglutinates *Proteus* OX19 although they do not have typhus fever. The peak of the response usually occurs about the time

of early convalescence; thereafter, it declines rather rapidly and in most instances below significant levels within three months after onset. No etiologic relationship has been demonstrated between these strains of *Proteus* and typhus fever. Castaneda, in 1934, demonstrated a carbohydrate antigen common to OX19 and *R. prowazeki*. The reaction is, therefore, empiric, but none the less a very useful one because of its simplicity.

The discovery by Cox (1938) that *R. prowazeki* could be grown in the yolk sac of developing chick embryos, made it possible to prepare large amounts of antigen for serologic tests. Complement-fixing antibodies appear in the sera of patients as early as the fifth to seventh day of illness. They increase in titer, reaching a peak in the first two or three weeks of convalescence. Thereafter, the titer falls slowly over a period of several months to low values, which may persist for years. Plotz and others (1943) described a method for the preparation of purified complement-fixing antigens from infected yolk sacs which would permit differentiation between epidemic and murine typhus. This differentiation, however, depends upon carefully standardized antigens and is not routinely available in diagnostic laboratories. It is now also possible to test sera of suspected cases of typhus for specific agglutination with suspensions of rickettsia. The time of appearance of these antibodies is approximately the same as for complement-fixing antibodies.

**Inoculation of Experimental Animals.** Monkeys, guinea pigs, rats, rabbits and other rodents are susceptible to experimental infection with *R. prowazeki*. Because of ease of handling and characteristic reaction, the guinea pig is the animal of choice in most experimental work. The infection may be established in guinea pigs by the intraperitoneal inoculation of blood taken from a typhus patient early in the febrile period. It is advisable to allow the blood to clot and to separate the serum for use in serologic tests. The clot is then ground with equal volume of sterile saline skimmed milk or nutrient broth. After allowing the suspension to stand until large particles have settled out, 4 or 5 ml. are injected intraperitoneally into a male guinea pig weighing at least 500 gm. Rectal temperatures are taken daily. After an incubation period varying from one to three weeks, a definite rise in temperature to 40° C or more indicates a probable infection. The temperature remains elevated for a few days and then returns to normal. To propagate the infection, blood is obtained by intracardial puncture or by killing the animal on the third or fourth day of fever and removing the brain and spleen. One of these organs is emulsified with normal saline and 1 to 2 ml. of suspension used for intraperitoneal inoculation of guinea pigs for the next passage. Guinea pigs survive typhus infection unless the infective dose is massive. Ordinarily, there is no visible scrotal reaction; strains of epidemic louse borne do not exhibit the Neil-Mooser reaction (Mooser, 1928). The infected guinea pig does not develop a positive Weil-Felix reaction. Both the white rat and wild rat can be experimentally infected. In these animals the infection is inapparent but they develop antibodies which can be demonstrated by the complement-fixation test.

**Transmission by Lice.** Transmission of typhus by the louse (*Pediculus humanus humanus*) was first demonstrated experimentally by Nicolle and others (1909). Their observations were confirmed by Ricketts and Wilder in 1910 and Anderson and Goldberger in 1912, and others.

This was the starting point of a series of investigations during World War I by von Prowazek; da Rocha-Lima; Otto and Dietrich; Nicolle; and by Wolbach and

iates (1922), and others, which revealed the essential biologic relationships between human typhus and to the causative agent, *R. prowazeki*, named in honor of Ricketts and von Prowazek, who as a consequence of their researches contracted the disease and died.

When lice are fed upon a typhus patient during the febrile period of the illness, a large proportion become infected with *R. prowazeki*. The organisms enter the cells lining the intestinal tract of the louse where they multiply. The parasitized cells are shed and the organism may then be passed in the feces of the louse or may enter the cells lining the intestinal tract. Rickettsiae appear in the feces of typhus-infected lice about three to five days after the first infective meal. Rickettsiae have been demonstrated in louse tissues, such as the salivary glands. The louse usually succumbs to the infection after 7 to 10 days. The course of typhus infection in human head louse *Pediculus humanus capitis* is the same as that in the body louse *Pediculus humanus corporis*. The latter is far more important in epidemic transmission.

Apparently the infection is transmitted to human beings by fecal contamination of a wound made by the louse in feeding or made by the host in scratching. In the feces, rickettsiae may survive for years under experimental conditions if temperature and humidity are kept low. Since the clothes of patients are frequently contaminated heavily with louse feces, it has been suggested that infection is occasionally transmitted by the air-borne route to the respiratory tract of a susceptible person. That it is possible to infect human beings by the respiratory route has been proved by laboratory experience. Several instances are on record where laboratory workers have acquired typhus as a result of laboratory accidents in which material containing rickettsiae was dispersed into the air by a Waring Blendor or by the bite of a mouse during the procedure of intranasal instillation. But while air-borne transmission is theoretically possible, it is relatively unimportant under conditions of actual exposure (Davis, 1947). The common mode of transmission without doubt is the inoculation of a louse bite with louse feces containing rickettsiae.

**Epidemic Propagation.** The elucidation of the role of the louse in transmission defined the epidemiology of typhus. Propagation is maintained in human populations by the circulation of lice from person to person. The louse is a relatively inefficient vector, since it has a very short range of movement; it crawls and does not fly. It must reach a susceptible noninfected human being within two weeks after an infective feed to be successful in transmission. There is no generation to generation transfer of *R. prowazeki* through the egg. It follows that epidemic spread is maintained by the existence of a large louse population on human beings who are crowded together in their living or sleeping quarters. Whether the louse or the human being is to be regarded as the source of the infection depends upon point of view. The situation is humorously depicted by Zinsser in his "Rats, Lice, and History" as follows: "The louse shares with us the misfortune of being prey to the typhus virus. We can dread, the nightmare of their lives is the fear of some day inhabiting an infected . . . human being. For the host may survive; but the ill-starred louse that has his haustellum through an infected skin, and imbibes the loathsome virus with his nourishment, is doomed beyond succor. In eight days he sickens, in ten days he is *in extremis*, on the eleventh or twelfth his tiny body turns red with blood, he is evacuated from his bowel, and he gives up his little ghost. Man is too prone to

look on all nature through egocentric eyes. To the louse, we are the dreaded enemies of death. He leads a relatively harmless life—the result of centuries of adaptations; then, out of the blue, an epidemic occurs; his host sickens, and the world he has ever known becomes pestilential and deadly; and, if as a result of circumstances not under his control, his stricken body is transferred to another whom he, in turn, infects, he does so without guile, from the uncontrollable need for nourishment, with death already in his own entrails. If only for his fellowship with us in suffering, he should command a degree of sympathetic consideration.”

**Seasonal and Geographic Distribution.** Typhus is more or less continuous, propagated among primitive people living in the colder climates, who because of their poverty, lack of facilities for maintaining personal cleanliness, and the character of their clothing are accustomed to infestation of lice. These conditions are realized in many parts of the world—in Russia, Poland, Siberia, southeastern Europe, Asia Minor, China, North Africa, Mexico and the Andean regions of South American countries. Transmission occurs during all months of the year, but incidence increases in the colder months as a result of the crowding together and lack of bathing, etc.

From these primitive native populations, among whom the disease is more or less constantly prevalent, it is propagated from time to time to adjacent human communities where conditions for spread are temporarily favorable. Such conditions are realized particularly among military and refugee populations during the disturbed conditions of wars.

Historically, typhus has been associated with war, disaster and famine. This was tragically illustrated by experiences in Europe during World War II, particularly in Germany. How devastating the disease can be under such disturbances has been described by Gordon (1948). Similarly, epidemics raged over Japan and Korea in 1945 to 1946 (Scoville, 1948). During this period, over 30,000 cases of epidemic typhus fever were reported. No prefecture of Japan nor province of Korea escaped. The case fatality rate was 6 to 10 per cent.

During the nineteenth century, typhus was frequently imported into the United States with the arrival of shiploads of infested immigrants. Localized epidemics were precipitated but after the middle of the century conditions were evidently not favorable to its continuous propagation in this country. During the Civil War, in 1861 to 1865, it was an unimportant cause of morbidity. The last epidemic in the eastern United States was caused by the importation of immigrants in New York City in 1893. Since then, except for an occasional case imported from Europe or Mexico and a small outbreak among the Navajo Indians in 1915, the United States has been free from louse-borne typhus. There are not enough lousy people in this country to support passage of the disease agent.

**Vaccine.** Many methods have been tried for producing suspensions of rickettsiae in adequate quantities to be used for vaccination. In 1933, Weigl attempted active immunization by using the phenolized intestinal contents of lice infected per rectum with *R. prowazeki* obtained from the brains of guinea pigs. The technic of infection is difficult. Two or three hundred lice are necessary to provide sufficient vaccine for one person; large scale immunization by this method is not practical. Castaneda (1938) and Durand and Giroud in 1940 used suspensions made from infected rodent lungs inactivated by the addition of formalin. Blanc and Baltazard, in 1941, &

ed a method of obtaining a suspension of attenuated murine typhus rickettsiae from flea feces. Since this vaccine contained living rickettsiae, immunity was developed at the price of development in the patient of an active, usually inapparent, infection. In 1940, Cox and Bell prepared an epidemic typhus vaccine based upon use of tissue culture. This vaccine consisted of a killed suspension of *R. prowazekii* grown on the yolk sac membrane of the chick and purified by centrifugation. Concentration of the effective antigenic material led to a vaccine which is satisfactory not only from the point of view of potency but also with respect to commercial production. Epidemic typhus vaccine used by the U. S. Army during World War II consisted of 10 per cent yolk sac suspension with the Breinl strain of *R. prowazekii* extracted by ether. The vaccine contains both rickettsial bodies and the antigen. Two doses of 1 ml. each are given, preferably separated by an interval of one month. The protection afforded is thought to last for six months or more. Stimulating or booster doses should be given at least annually or before entering an area of exposure.

A critical evaluation of protection afforded by this vaccine under conditions of actual exposure is not yet available. The evidence gathered from various observations leads to the conclusion that the risk of attack is reduced, the course of the disease is modified, and that the probability of a fatal issue is decreased (Gilliam, 1947; Sadusk, 1947). In addition to this, there is the important observation that man can be infected with difficulty, if at all, when permitted to feed upon a patient with typhus who has been previously vaccinated.

**Control of Epidemics.** In the presence of a typhus epidemic, the first step is to make provision for early diagnosis of cases and case finding. All reported cases should be immediately investigated. If the patient is found to have fever, headache, the characteristic rash, the house should be temporarily quarantined. The patient and familial contacts, their clothes and bedding, should be disinfested with dusting. While the members of the family are restricted to home for 14 days, infected cases of typhus fever should be removed to an isolation hospital. On being admitted to the receiving ward at the hospital all clothing should be removed immediately from the patient, dusted with DDT powder, and stored in a suitable container. The hair of the head, axillary and pubic regions should be collected and destroyed. The patient is then bathed, given clean bedclothes and sent to an isolation ward. Proper provision should be made for medical care of patients with antibiotic resistance. If possible, typhus immunes should be employed as attendants in the hospital. In any event, they should be properly instructed as to the danger of infection. Bed lice, should receive typhus vaccine at frequent intervals, and be kept under continual supervision.

**Local and Zonal Delousing.** Louse disinfestation squads or dusting teams should be organized for mobile operations. The first point of attack is the household of the patient and his immediate associates. Disinfestation should be extended as rapidly as possible to the neighboring family groups and concentrated upon the neighborhoods or zones in which cases are reported. Dusting of these persons, their clothes and bedding, should be done in their homes. As opportunity develops, the disinfestation should be extended to include as much of the population as practical to reduce the total amount of lousiness in the community.

Vaccination teams should be organized consisting of a doctor, nurse and clerk. Their responsibility is to vaccinate all persons in a focal area except the patient. Under epidemic conditions, it will probably be necessary to give two doses of vaccine, one week apart. These preliminary inoculations should be followed by a "booster" dose one month later if it seems practical. Such measures are apparently effective in bringing epidemics to an end (Wheeler, 1946; Gordon, 1948; Scoville, 1948).

**Control During Inter-Epidemic Periods.** Epidemic typhus decreased and disappeared from many parts of the world as civilization advanced and lousiness of the population decreased. It is a socio-economic problem as it is so closely woven with primitive living conditions, squalor, ignorance, and poverty.

That it is possible to temporarily reduce louse infestation of a community has been demonstrated by Montoya and Osejo (1948) using DDT and phenylcellosolve in control of pediculosis in Colombia. Application of these insecticides to 98 per cent or more of the population reduced louse infestation rate of 65 to 70 per cent to 5 per cent or less. These authors advanced the hypothesis that this level, if maintained, was sufficiently low to preclude typhus outbreaks and reduce the incidence of the disease to a position of minor public health importance. However, in order to maintain this low level, it would be necessary to repeat the delousing operation on the whole population at intervals every three or four months, unless their conditions of living were improved.

## RECRUDESCENT TYPHUS

*(Brill's Disease)*

In 1910, Dr. Nathan Brill called attention to a typhus-like disease occurring in New York City. It was similar to typhus in its clinical course but relatively mild in the case fatality rate was less than 1 per cent. He noted that it seemed to appear especially among Jewish immigrants from southeastern Europe. It showed no tendency toward familial spread. The disease was sporadic and occurred more frequently in the summer months than in the winter. He was inclined to believe that he was dealing with a new clinical entity and called it "An infectious disease of unknown etiology." In 1912, Anderson and Goldberger were successful in the inoculation of a rhesus monkey with the blood from a case of Brill's disease in New York. They found that infection rendered monkeys immune to subsequent inoculation with the same passage virus. Furthermore, monkeys that were previously infected with murine typhus were found to be immune to Brill's disease and vice versa. From these observations, they concluded that Brill's disease was in fact identical with louse-borne typhus fever. Following these publications, there were reports of cases of Brill's disease from scattered cities in the United States. Even though these cases could not be traced directly to contact with a recently imported case of typhus, it was assumed that they originated either from infected lice or clothing contaminated with louse feces brought into this country by immigrants from European areas in which epidemic typhus existed.

Later studies of endemic typhus in southeastern United States (Maxcy, 1926a), suggested that it was similar to Brill's disease clinically and epidemiologically; in other words, that Brill's disease was actually murine typhus. However, Zinsser (1934) isolated from cases of Brill's disease in Boston, by animal inoculation, three strains of typhus, all of which corresponded in every respect to the louse-borne type, but the male guinea pigs did not exhibit the Neil-Mooser reaction. He then reviewed the epidemiological distribution of those cases of Brill's disease in New York and Boston up to 1934. He was able to obtain records of 538 such cases and found that 100 per cent occurred in individuals of foreign birth, 90 per cent were of a single ethnic group, Jews, 94 per cent of whom were born in those regions of southeastern Europe in which typhus had been endemic and often epidemic. Of 126 cases about which data were available, 76 per cent had been in this country over 10 years, the remainder from 1 to 10 years; in only two could the origin of infection be attributed to immediate contact with foreign sources. No connection whatever could be traced between cases and there was no domiciliary or occupational association. To explain this selection, Zinsser advanced the hypothesis that the cases observed in New York and Boston represented recrudescences of infections originally acquired many years previously when the individual had been living in a European country where typhus had been epidemic. He suggested that recrudescence cases might serve to maintain continuity of prevalence by bridging breaks in the chain of man-lice propagation, and that this was the manner in which the European virus had survived in continental foci for centuries.

In 1943, Plotz reported that the sera of 23 patients with Brill's disease gave higher titers in the complement-fixation test with classical epidemic antigen than with the murine antigen. Furthermore, the epidemic antigen completely absorbed

the agglutinins from the sera of Brill's disease while the endemic antigen only partially removed these agglutinins. It has also become apparent that Weil-Felix reaction may be negative or only doubtfully positive in many cases of Brill's disease (Schoenbach, 1949). Recently, Murray and others (1950) carefully studied patients with Brill's disease located in hospitals serving communities with large numbers of foreign-born Jews. Seven of these came under observation on the fifth to eighth day of illness. All were foreign-born Jewish immigrants. Six of the seven patients gave a history of having had a typhus-like illness while living in Europe. Probably little significance can be attached to the usual patients' recollection of previous typhus. Price (1955) has reported the recovery of *Rickettsia prowazekii* from lymph nodes of two patients who had migrated to the United States from Russia more than 20 years previously and who had had no known exposure to infection since that time. Serological tests showed them to have complement fixing and virus neutralizing antibodies to *R. prowazekii* before and after a surgical operation. In each of these seven cases, diagnosis of Brill's disease was established by clinical observation and laboratory data. In each instance, body lice fed upon the patient during the first week of illness were found to be infected with typhus rickettsiae. These seven strains were carefully studied on experimental animals by cross immunity tests and by serologic tests (Murray and Snyder, 1951). The results indicated that all seven had the characteristics of *R. prowazekii*. These observations added confirmation to Zinsser's hypothesis that patients with recrudescent attacks of latent infection residing in louse-infested communities provided a mechanism of interepidemic survival.

#### MURINE TYPHUS

(*Endemic Typhus, Flea-Borne Typhus*)

Following the identification of Brill's disease with Mexican typhus by Anderson and Goldberger in 1912, there appeared from time to time reports of sporadic cases of what appeared to be mild typhus in scattered localities of the eastern and southeastern United States, in the Federated Malay States and in Australia. Maxcy (1926a, b) reviewed these reports and presented the results of the clinical, etiological and epidemiological observations on 197 cases collected in Alabama and the City of Savannah, Georgia, between 1922 and 1925. On the basis of the assembled evidence, he concluded that a disease clinically indistinguishable from typhus fever

cept with regard to its relative mildness and low fatality rate, was endemic in the theastern United States. The epidemiological characteristics were at variance with the concept of man-to-man transfer by lice. An hypothesis that seemed to afford a more probable explanation of the mode of transmission was that a reservoir of infection existed other than in man, and that this reservoir was in rodents, probably rats or mice, with accidental transmission to man through the bite of some parasitic bloodsucking arthropod—fleas, mites, or possibly ticks. This hypothesis was subsequently explored by many investigators in this country and abroad, leading to a relatively complete understanding of the disease now known as murine typhus.

**Clinical Course.** The onset is fairly rapid with chills, fever, headache, and nausea. The eruption usually appears about the fifth day; it may appear as early as the second or as late as the ninth day. The evolution of the eruption is rapid, becoming general in the course of 24 hours. The soles of the feet and the palms of the hands are usually spared. At first erythematous in character, as the eruption increases the color changes from a dull red to a darker hue with a purplish tinge and some petechial spots. It reaches maximum intensity in four to six days and begins to subside. In the majority of instances the skin becomes clear by the time convalescence is established. In the milder cases the eruption may be extremely evanescent, limited to a few spots scattered over the body which are visible for only a few hours when the temperature is elevated. The occurrence of cases without eruption seems highly probable but their frequency is unknown. The patient may have a slight hacking cough. In the early stages, nausea, vomiting, refusal of food are common manifestations. In about one fifth of the cases the sensorium remains clear throughout the illness. In the remaining four fifths the degree of involvement varies from slight dullness and apathy, or a combination of dullness with nervousness and irritability. In about one third of the cases there is delirium at some time during the course of the illness; it varies from night terrors to a complete disorientation and confusion. In the very severe cases, which are occasionally encountered, particularly in old people, the patient may go into coma and die during the latter part of the second week. One of the most striking features of the disease is its uniform duration. An analysis (Maxcy, 1926b) of 94 cases showed that 36 per cent terminated between the third and fifteenth days and 86 per cent between the twelfth and sixteenth days. Four of the 94 cases reached normal about the tenth day (abortive cases) and four complicated cases remained ill for 21 days or more. Although the illness lasts but a few weeks, a patient is usually prostrated and in a weakened condition at its termination. Not infrequently it is another week before he can get out of bed and a month or two before he can resume work. He is likely to be nervous and depressed for some time.

**Laboratory Diagnosis.** The differential and total count of white blood cells are generally within normal range. The serum shows a rising titer of agglutinins for *Brucella* OX19 (Weil-Felix reaction) beginning about the end of the first week and reaching maximum during convalescence. A rise in titer to a dilution of 1:160 or higher is regarded as significant. In similar manner, a rise in titer for a complement-fixing antibody for rickettsial antigens occurs. It is possible to standardize the antigen so that it will distinguish between antibodies specific for epidemic (louse) typhus and for murine typhus. Specific agglutination of rickettsial antigens is less frequently

used. Recovery of the causative agent by inoculation of experimental animals is not a practical procedure for the ordinary diagnostic laboratory.

**Inoculation of Experimental Animals.** Reference has previously been made to the inoculation of experimental animals with epidemic typhus. The causative agent usually can be recovered by inoculation of a guinea pig with an emulsion of blood clot obtained from the patient in the first week of his illness. The guinea pig shows a febrile reaction of the same character as that observed with epidemic typhus but differing in that on passage in male guinea pigs the scrotal reaction (Neil-Mooser) is constantly observed during the height of the fever. Guinea pigs recovering from an infection with murine typhus are solidly immune to epidemic typhus and vice versa. In smear preparations made from the exudate stained with Giemsa, or the method described by Macchiavello, the causative agent, *R. mooseri*, can be demonstrated in large mononuclear cells. In its morphology it is indistinguishable from *R. prowazeki*.

**Arthropod Transmission.** The work of Dyer and his associates in 1931, established that the tropical rat flea, *Xenopsylla cheopis*, is the principal vector of murine typhus from rat to rat and from rat to man. *R. mooseri* were recovered from fleas taken from wild rats caught on premises where cases of murine typhus had occurred. Experimentally, it was found that *Xenopsylla cheopis* becomes infected with *R. mooseri* when allowed to feed on typhus-infected rats; that infected fleas readily transmit typhus from rat to rat; that the rickettsiae are present in the feces of infected fleas; that the rickettsial infection may be transmitted by rubbing the feces of infected fleas into the abraded skin of guinea pigs and that infected fleas may retain the infection for at least 52 days. These observations have been supplemented and confirmed by many investigators. Rickettsiae are found multiplying in the gut cells and malpighian tubules but not in the salivary glands of the flea. Up to the present no one has demonstrated transovarial passage from one generation to another in fleas.

Other fleas found upon rats can be infected experimentally, viz., *Leptopsylla segnis*, the mouse flea; *Nosopsyllus fasciatus*, rat flea; *Echidnophaga gallinacea*, chicken flea; and *Ctenocephalides felis*, the cat flea. This is also true of a rat mite *Liponyssus bacoti*, and of a rat louse, *Polyplax spinulosa*. There have been reports of recovery of typhus virus from specimens captured in nature of the chicken flea, the cat flea, and the rat mite, *L. bacoti* (Kohls, 1948). Thus, while several arthropods could act as vectors from rat to rat, their importance in maintaining the infection in rat populations in nature is unknown. The geographic and seasonal distribution of murine typhus corresponds to what is known about the seasonal and geographic distribution of the tropical rat flea, *X. cheopis*. This flea is also known to change hosts and to attack man, and is apparently the principal vector concerned in transmission of the disease.

**Rodent Reservoir.** During the same year that Dyer and his associates recovered a murine strain of typhus rickettsiae from an emulsion of rat fleas, Mooser and others (1931) isolated a similar strain from the brain of a rat trapped in Belknap prison in Mexico City. Experimentally inoculated, the Norway rat has an inapparent infection manifested by the development of a positive Weil-Felix test and a positive complement-fixation reaction and by immunity to subsequent inoculation with homologous material. In 1938, Pailip and Parker recovered the agent from brain

white rats 370 days after original infection. How long such animals remain active for their ectoparasites has not yet been determined.

The value of the complement-fixation test as an indicator of past infection in commensal rats was established by Brigham and Bengtson (1945) who found from 0 to 81 per cent sera positive in rats captured in certain southern cities. This method has been found extremely useful in establishing focal infection in rat populations and following the course of the enzootic in relation to control measures. In San Antonio, Texas (Davis, 1948), 34.7 per cent of adult roof rats (*Rattus rattus*), 51.4 per cent of adult brown rats (*Rattus norvegicus*) positive for typhus complement-fixing antibodies.

In addition to domestic rats, house mice (*Mus musculus* and *Mus wagneri*) and the field mouse (*Peromyscus polionotus*) have been found infected in nature. A wide variety of rodents and other small domestic and wild animals have been found susceptible to experimental infection (Brigham and Dyer, 1938; Philip, 1948). In a limited survey of animals, exclusive of commensal rats, in southwest Georgia, 3,202 sera from 37 species were examined by the complement-fixation test for murine typhus (Morlan and others, 1950). Sera from 12 species of animals, including the opossum, cotton tail rabbit, fox squirrel, house mouse, rice rat, cotton rat, old field mouse, cotton rat, dog, Florida skunk, weasel, and blue jay, were found to be positive in low titers. Rickard (1951) presented evidence that the finding of positive complement-fixation tests up to a dilution of 1:64 with the sera from caught cotton rats, was not of specific significance and did not indicate previous experience with murine typhus. Accordingly, it cannot be assumed that positive complement-fixation tests in low titers in various species of birds and animals necessarily indicate such an infection. Up to the present, therefore, there is no convincing evidence of the existence of a reservoir of *R. mooseri* in animals other than the commensal rat, although the infection may occasionally be passed to associated wild rodents.

**Prevalence.** The biological mechanism involved in the maintenance of murine typhus in a natural environment is now clear, at least in outline. The principal and probably only reservoir of infection of consequence is in commensal rats. In this species, the infection is propagated from the infected animal to the susceptible by the mediation of ectoparasites, but particularly by *Xenopsylla cheopis*, the tropical rat flea. Occasionally, man is accidentally infected by a rat flea which has strayed from its natural host. The frequency of occurrence and distribution of the disease among human populations is thus conditioned by several factors, the principal ones of which are the following: (1) the relative numbers of commensal rats in the community; (2) the number of ectoparasites per rat, with particular reference to *Xenopsylla cheopis*; (3) the frequency with which the infection is being transmitted from infected to noninfected rats; (4) the extent and intimacy of exposure of human beings in a community to tropical rat fleas. The possibility of transmission from rat to man by the rickettsiae in flea feces through the air-borne respiratory route is a remote possibility, but the relative importance of this mechanism is unknown.

Commensal rats are concentrated upon premises where food, water and harborage are available. In towns and cities generally, these conditions are realized, especially in the older business sections. The risk of infection is, therefore, generally greater among persons employed in handling food, employees of groceries, butcher

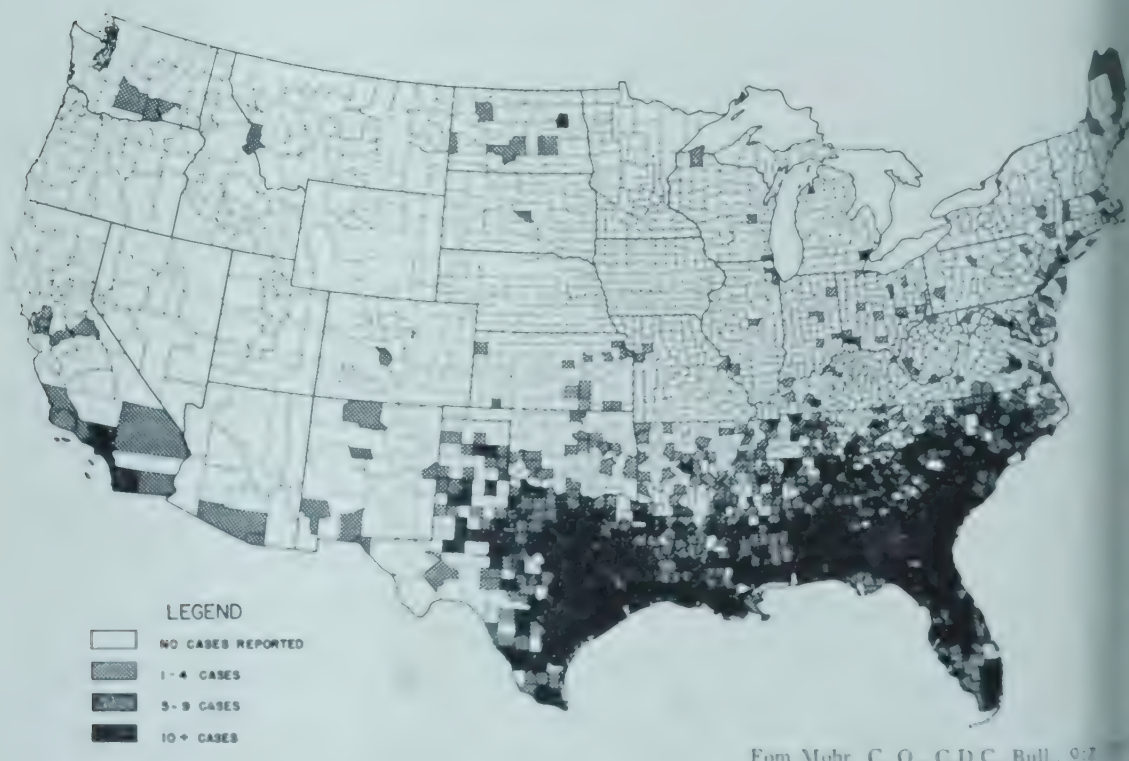

shops, seed stores, markets, etc. For this reason, cases of murine typhus are apt to be more frequent among males than females and relatively more frequent among adults than children. Local variations determine the exact pattern.

Seasonally, the incidence of murine typhus in human populations is greatest during the summer months, decreases in the fall, and reaches a low point during the middle of the winter. This is apparently determined by the numbers and activity of fleas, particularly of *Xenopsylla cheopis*, in relation to temperature and humidity and their access to man.

The disease is by no means limited to urban communities, since in many rural areas crops such as peanuts and corn afford abundant supply of food for commensal rats and consequently many rural homes are heavily infested.

During the two decades following the discovery of murine typhus in the southeastern United States, the number of cases recognized and reported by physicians increased annually, and the geographic area involved was extended. The peak was reached in 1944, when the total number of cases reported was 5,213, most of them occurring in nine southeastern states and in southern California (see Fig. 6-3). Since that time there has been an abrupt decrease. To what extent this is due to

From Mohr, C. O., C.D.C. Bull., 9:7

Fig. 6-3. Reported cases of endemic typhus fever in the United States, 1941 through 1954.

natural trend downward of the rat and flea population or to active control measures is unknown. Very recently, the decline has been accelerated by more exact diagnosis with laboratory confirmation. There were only 163 cases in 1954.

Since the original observations, natural infection of commensal rats with murine typhus has been demonstrated by recovery of strains or by serological procedures.

Jamaica, Brazil, Colombia, Peru, the Mediterranean basin, Russia, Poland, Germany, Rumania, Manchuria, North China, Malaya, the Philippines, Indochina, India, South Africa, Java and Australia.

**Control.** Since the disease is not contagious from man to man, there is no need for isolation of patients nor for restrictions upon the movements of household associates. In the hospital, cases can be treated on the open wards without special precautions. Chloramphenicol (chloromycetin) (Smadel, 1949) and aureomycin (Hoenbach, 1949) are reported to be effective in shortening and alleviating the severity of the disease.

The occurrence of a human case is a signal of the existence of an enzootic among feral and feral rats. The first step in control is to ascertain, if possible, the location of the place of exposure, whether at work, at home or at some place temporarily visited. A careful history is taken of the movements of each patient during the time period from 6 to 14 days preceding the onset of his symptoms, and this information is utilized, foci of infection may be located by common experience. Suspected premises should be immediately dusted with DDT for suppression of rat fleas; subsequently, rat control measures are undertaken. Persons exposed to infection on the premises may be given murine typhus vaccine to reduce the risk of the disease. While these measures are indicated in emergency situations, the prevention of murine typhus, as of bubonic plague, will depend upon measures conducted over a long period of time to reduce the rodent and flea populations in a community. It has been demonstrated (Hill and Morlan, 1948) that in an area where the probability of rural residents acquiring typhus fever was equal to or greater than that for residents of some urban communities it is possible to control this disease by the county-wide application of 10 per cent DDT in pyrophyllite to rat runs and harborage. In the absence of other rodent ectoparasite or typhus control measures, the murine typhus fever incidence was significantly reduced in two counties in Georgia, as was shown by comparison with previous experience in these counties and by concurrent comparison with data from an adjacent county.

## ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever was known along the Snake River in Idaho as early as 1873, but the first clinical description of the disease in a medical journal was given by Maxey (1899). He noted that the disease occurred invariably during the spring months and was contracted by persons while residing or sojourning in or near the mountains, and that it was much more common in men, occurring most frequently among prospectors, miners, sheep herders, and cattlemen. Wilson and Chowning, in 1902, suggested that the wood tick was the transmitting agent, and that an animal reservoir existed. Ricketts, in 1906, began studies which demonstrated the presence of infected ticks in nature and the hereditary passage of the virus from one generation of ticks to the next. McCalla, in 1908, published the results of an experiment performed in Boise, Idaho. He removed a tick from a spotted fever patient and produced the disease in two volunteers by permitting the tick to feed on them. Ricketts, in 1909, reported successful transmission of spotted fever by the wood tick, *Dermacentor andersoni*, and described the micro-organism which he had observed in smears prepared from the blood of man, monkey, guinea pig, and from the tissues of the tick. The following year, Ricketts and Wilder showed by cross immunity experiments that Rocky Mountain spotted fever and typhus were separate and distinct entities. Wolbach (1919) reported the results of his careful etiologic and pathologic studies and named the causative organism *Dermacentor xenus rickettsi*. He called attention to the intranuclear multiplication of rickettsiae in tick tissue.

Up to 1930, it was thought that Rocky Mountain spotted fever was confined to 11 states of the northwest, although one case had been reported in Indiana. In connection with field investigations of typhus in the southeastern United States it was noted that cases living in the rural districts in the northern tier of states and urban dwellers vacationing in the country suffered from a very severe disease which did not exactly correspond to the clinical picture of endemic typhus. A high proportion of these cases gave history of tick bites within a short time preceding onset. Davis and others (1931) noted that many cases observed during the spring and summer of 1930 differed clinically from the disease as described by Brill, Maxey, and others and closely resembled Rocky Mountain spotted fever. Two strains of virus, established in guinea pigs from the blood of cases occurring in a rural section of northern Virginia, were subjected to intensive study with the result that they were found to be immunologically indistinguishable from a strain of spotted fever isolated from ticks in the Beaver Root Valley of Montana. Since that time, Rocky Mountain spotted fever has been shown to be widely distributed in the United States and present in two provinces of western Canada, and in two states of Brazil (exanthematic type of Sao Paulo) and in Colombia, South America (Tobia fever).

In the eastern and southern United States, the common dog tick, *Dermacentor bilis*, was found to be the vector. There is some evidence to indicate that dogs contract the infection in an inapparent form. In the southwest United States, have also been traced to the lone star tick *Amblyomma americanum*; in Brazil common vector is *Amblyomma cajennense*. Many other tick species have been found to be experimentally infectible but epidemiologically unimportant in transmission of the human disease (Kohls, 1948).

**Clinical and Pathological Features.** The clinical course of the human disease is similar to that described for typhus fever. In severe cases of spotted fever the rash tends to be more hemorrhagic and to be accentuated on the extremities, particularly at the wrists and ankles. Occasionally, a lesion may be detected at the site of the bite, but a typical primary eschar is lacking. Nervous and mental symptoms are common; restlessness, insomnia, disorientation, and delirium are manifestations of involvement of the central nervous system. Prostration may be extremely marked in the beginning, merging into coma, with death as early as the sixth to eighth day. Convalescence is apt to be slow, and may be complicated by visual hallucinations, deafness, and mental confusion. Although recovery may be delayed, it is usually complete in the end. The case fatality rates vary directly with age, as in typhus, and there is also considerable variation in the virulence of strains in different parts of the country. The crude fatality rate for reported cases in the United States is about 18 per cent. Recent reports indicate that the early institution of treatment with antibiotics—chloramphenicol (chloromycetin) and aureomycin—greatly lessens the course of the disease and decreases the risk of death (Ross and others, 1948; Pincoffs and others, 1948).

**Laboratory Diagnosis.** Confirmation of the diagnosis is afforded by the Weil-Felix reaction which becomes positive with *Proteus* OX19, usually with OX2, and sometimes with *Proteus* OXK during the second week of the illness. The complement-fixation test becomes positive about the same time. The causative agent may be isolated and identified by inoculation of guinea pigs with blood obtained from a patient early in the course of the illness. The incubation period of spotted fever in guinea pigs is four to five days but, as in typhus, it may be prolonged in the laboratory generation. The fever tends to be considerably higher than in typhus, ranging from 106° to 107° F. A fatal termination is common, although varying with different strains from 100 per cent to 0. With the more virulent strains there is scrotal necrosis. In others, this necrosis is inconspicuous and the scrotal reaction resembles that seen in guinea pigs inoculated with murine typhus. *D. rickettsii* may be grown in tissue culture and in the chorio-allantois and yolk sac of developing chick embryos. The rickettsiae are killed in a few minutes by exposure to moist heat at 50°C, to chemical agents, and in a few hours by desiccation at room temperature.

**Natural Propagation and Distribution.** Selection of the disease in the western United States for persons exposed to the open range and the seasonal limitation to spring and early summer months was explained when the tick vector species was identified as *D. andersoni*. This is a wood tick, which in the adult form is found widely distributed upon the large mammals, particularly cattle and sheep, in the western range country from the eastern portion of the Pacific Coast states to northern North and South Dakota, and from New Mexico on the south to Alberta, Saskatchewan, British Columbia, on the north. Adult ticks live two to four years or

more. Engorged females deposit their eggs in the soil. The winter is passed in the adult, nymphal or egg stage. Larvae or seed ticks emerge in the late spring and take a blood meal from small animals. If successful, they moult to the nymphal stage which may not become active until the following spring. Many small animals, especially rodents, are susceptible to infection with the virus of Rocky Mountain spotted fever, and after having been bitten by an infected tick develop an inapparent form of the disease. During the period of time that the causative agent is in the peripheral circulation, these animals serve as a source of infection for the uninfected larval, nymphal or adult ticks which chance to feed upon them concurrently. The rickettsiae pass through the stage to stage development of the tick and are carried to successive generations in decreasing numbers by transovarial passage. Infection is thus maintained in nature by the alternation of the small animal and tick host. Dogs and field mice (*Microtus pennsylvanicus*) appear to be important vertebrates in the transmission chain of *R. rickettsii* in Maryland (Price, 1954). A relatively large percentage of this species of field mice has been found to have specific complement fixing and toxin neutralizing antibodies to *R. rickettsii*.

The distribution of the disease in eastern and southern United States was explained when it was discovered that the vector is *Dermacentor variabilis*. The hosts of this species of tick are mainly domesticated animals, such as a dog, horse or cow. Therefore, exposure is common about areas of habitation. Accordingly, the disease occurs more frequently among children and females than is the case with the western spotted fever (Topping, 1941).

**Prevention.** Prevention depends primarily upon exercise of personal care and protection against tick bites. Persons who are exposed to known infected areas should frequently examine the clothing and body for ticks. Usually, the tick does not become attached to its host immediately but travels about for several hours. It has been shown that the chance of receiving infection from the bite of a tick is directly proportional to the length of time the tick has fed. Ticks should be removed from the person or from a pet with small forceps or with a piece of paper. The skin area involved should be swabbed with tincture of iodine and the forceps disinfected with heat or chemicals. Hands should be washed with soap and water after such operation.

A vaccine is prepared from rickettsiae grown in the yolk sac tissue of fertilized hen's eggs and inactivated by the addition of phenol 0.4 per cent and formalin 1 per cent (Cox, 1939). Evidence from animal experiments and from use in human beings indicate that the yolk sac preparation affords significant protection. It should be administered in the spring or early summer before the beginning of the tick season and should be repeated each year, since the maximum degree of protection conferred is less than a year. The degree of immunity afforded is relative, but the chance of subsequent infection is lessened and the risk of death is greatly reduced. The adult dose consists of two injections, 10 days apart, of 2 ml. each, child should receive half of this amount.

### BOUTONNEUSE FEVER

Connor and Bruch (1910) described a mild typhus-like fever which they believed to be an endemic disease of Tunis, North Africa, and proposed the name boutonneuse fever. It was subsequently observed to occur in the vicinity of Marseille, France. The disease was thought to resemble the mild typhus reported by and Maxcy in the United States. However, it was noted that somewhere on the body of each case could be found a small black eschar, "tache noir." The cases presented gave no history of louse infestation. At first it was thought to differ from Weil's disease by the fact that the Weil-Felix reaction was generally negative. More recently, however, it has been demonstrated that an increase in the agglutinins for *Brucella* OX19 can usually be found. Experimental evidence that the disease was transmitted by the common dog tick, *Rhipicephalus sanguineus*, was presented by and Conseil (1931). Cross immunity tests in guinea pigs (Badger, 1933) indicated that Boutonneuse fever and Rocky Mountain spotted fever were immunologically related if not identical. However, subsequent investigators pointed out that an ulcer was produced at the site of experimental bites by ticks infected with *Dermacentor rickettsii*, whereas an ulcer and the accompanying lymphadenopathy was constantly produced at the site of a bite of a tick infected with the agent of Boutonneuse fever. The latter was, therefore, designated *Dermacentor rickettsii*.

Boutonneuse fever is now known to have a wide geographical distribution. It has been reported from most of the Mediterranean countries and from the Crimea. Available evidence suggests that the disease described as Kenya typhus and South African tick-bite fever are probably identical with Boutonneuse fever, although caused by different species of ticks. A recent review has indicated the widespread distribution of this human tick-borne rickettsiosis in Africa.

### INDIAN TICK TYPHUS

In a series of publications between 1917 and 1927, Megaw and his associates drew attention to a typhus-like disease in India which differed from classical louse-borne typhus in its clinical and epidemiological characteristics. They occurred sporadically and in small groups of cases in widely scattered rural localities in the hills and scrub areas of Kumaon hills and Central India plateau. The season of occurrence appeared to be the winter in the less elevated regions and summer in the

higher regions. Patients had nearly always been exposed to bites of ticks, and in some cases the tick was actually found fastened to the body. The incubation period was from one to three weeks. Duration of fever was from 12 to 16 days in most instances but sometimes lasted as long as three weeks. The case fatality was low. The Weil-Felix reaction with *Proteus* OX19 was negative. The disease differed from Boutonneuse fever and from scrub typhus in the absence of any local ulcerated sore (eschar) and local lymph adenitis. For these reasons, and because it seemed to resemble Rocky Mountain spotted fever somewhat, it was called Indian tick-typhus by Megaw, although at no time was experimental evidence produced which definitely incriminated the tick as a vector. Recently, Topping and others (1943) reported the results of complement-fixation tests on three sera obtained from patients in Mysore State which indicated the causative agent was more closely related to spotted fever than to the typhus group.

### SIBERIAN TICK TYPHUS

Reports from Russian workers indicate the occurrence of a typhus-like, tick-borne fever in central and eastern Siberia. Sera of patients give a positive Weil-Felix reaction to *Proteus* OX19. The principal vector is *Dermacentor nuttalli*. The rickettsial agent has been demonstrated from ticks collected in nature and natural infection has been found in certain small rodents. The relationship of rickettsial strains recovered from these sources to *Dermacentroxenus rickettsii* and *conori* has not been established.

### SCRUB TYPHUS

#### (*Tsutsugamushi* Disease, *Mite-Borne Typhus*)

Typhus-like fever ascribed to the bite of a minute insect was known to natives of certain river valleys in Honshu, Japan, almost a century ago. K. Tana (1899) presented a careful description of its clinical and epidemiological features and identified the vector as a mite found in large numbers in the infected valleys during the summer months when most of the cases occur. From 1906 to 1922 tsutsugamushi disease was the subject of intensive investigation by Japanese scientists. In the meantime, typhus-like fevers had been described under many names endemic in localities scattered throughout southeast Asia and the adjacent archipelago. As the result of many studies (Blake and others, 1945), it has become clear that these belonged principally to two categories: (1) murine, or flea-borne typhus

ch the sera from patients agglutinate *Proteus* OX19, and (2) mite-borne or scrub typhus, indistinguishable from tsutsugamushi disease, in which the sera from patients give a positive Weil-Felix reaction with *Proteus* OXK. The latter disease has been recognized as occurring in Formosa, the Pescadores Islands, the Philippines, India, Federated Malay States, Burma, India, Ceylon, Sumatra, Java, New Guinea and adjacent islands, and Northern Queensland, Australia. During World War II, scrub typhus was far more important as a cause of morbidity and mortality in military forces operating in the southwest Pacific area and in the China-Burma-India theater than was louse-borne typhus to the forces operating in the Mediterranean and European Theaters.

**Clinical Course.** The distinguishing characteristics of this form of typhus is the absence of the primary lesion, or eschar, usually single, sometimes multiple, at the site of the infective mite bite or bites. Although not always present, an eschar can usually be found by careful examination somewhere on the patient. The eruption is more erythematous, macular and evanescent than in louse-borne typhus. While the course of the fever may be terminated in two weeks, it is not unusual for it to last three or four weeks. More or less extensive pneumonitis is common and lesions of the myocardium may give rise to impairment of cardiac function, sometimes circulatory failure. Case fatality rates vary in different geographic areas from about 2 per cent to 20 per cent. Prognosis becomes increasingly grave with advancing age.

**Laboratory Diagnosis.** Laboratory confirmation of the diagnosis is afforded by the Weil-Felix reaction becoming positive during the second week of the disease. The reaction is positive to *Proteus* OXK and commonly negative to *Proteus* OX19 and OX2. About the same time, complement fixation becomes positive with an antigen made from a suspension of *Rickettsia tsutsugamushi*. The etiologic agent can be easily recovered and demonstrated by intraperitoneal inoculation of mice with a minute amount of defibrinated blood obtained from a patient early in the course of the disease.

**Natural Propagation.** *Rickettsia tsutsugamushi* is primarily a parasite of trombiculid mites, of which two closely related species have been identified as vectors, *Neotrombicula kamushi* and *T. deliensis*. During the larval stage these mites attach and feed on various species of wild rodents and occasionally upon other animals, such as cats, marsupials and upon birds. Rodents have been found to be infected in nature with *R. tsutsugamushi*—*Microtus montebelli* in Japan, *Rattus concolor browni* in New Guinea, *Rattus concolor concolor* in Burma. Infection contracted by the larvae while feeding is passed by stage-to-stage transfer through the nymph, free-living adult and egg to the next generation. Since larvae feed only once upon a host, transmission from rat to rat to man requires transovarial passage of the *R. tsutsugamushi* in successive cycles of development of the trombiculid mite.

**Distribution and Prevalence.** It follows that the distribution of the human disease is determined by the ecology of the affected locality, i.e., with regard to the number of rodents, numbers and kinds of ectoparasite species of mites and the opportunities for the larval mites to make effective contact with human beings. The mites live in the upper layer of the soil in the organic detritus which covers it, and crawl for short distances up on the grass and other vegetation. Accordingly, the disease shows an occupational selection for the agricultural laborers working or digging in new or overgrown fields and abandoned plantations, explorers, prospectors, soldiers, etc. Its seasonal distribution is determined by climatic factors. In

Japan, it is limited to the four summer months, from June to September, while in tropical areas, such as New Guinea, transmission may occur throughout the year.

**Prevention.** In the treatment of cases, precautions with regard to isolation are not necessary. The handling of patients is much the same as that for other typhus-like fevers. The investigations conducted by Smadel and his associates (1950) have demonstrated very clearly that the course of the disease can be modified and controlled by the administration of the proper doses of chloramphenicol (chloromycetin) at proper intervals, and for a suitable length of time. Efforts to produce an effective vaccine have not been successful up to the present time (Berge and others, 1949) because of the diversity in antigenic composition of various strains of *R. tsutsugamushi*. Prevention of exposure depends upon protection from mite bites in an endemic area. A camp site should be cleared and the brush and grass burned before occupation. The individual may be protected by wearing clothing that has been treated with miticide chemicals. During World War II, methods were developed for impregnating uniforms in terminal laundry rinse and with a soap solution containing dimethyl phthalate and benzyl benzoate (Bushland, 1946).

#### OTHER RICKETTSIAL DISEASES

In recent years, two human diseases, and possibly a third, have been found to be due to rickettsiae; namely, Q fever, rickettsialpox, and trench fever. In each of these the clinical pattern is distinctive and cannot be classified as typhus-like.

#### Q FEVER

Derrick in 1937 investigated the occurrence of a series of cases of an unknown fever among slaughter house and dairy employees in Queensland, Australia. He described the clinical course in nine cases, and by inoculation with blood from each of the nine patients he was successful in establishing the infection in guinea pigs. No organism could be seen in or cultivated from human or guinea pig material, and it appeared likely that the infecting agent was a virus. Infected guinea pig liver was thereupon sent to Dr. F. M. Burnet of Melbourne, Australia, who in transferring the infection into mice was successful in discovering rickettsial bodies in their spleen. Subsequent work (Burnet and Freeman, 1937) established the rickettsial etiology of this disease and the organism was named *Rickettsia burneti* by Derrick in 1941.

In another part of the world, about the same time, Davis and Cox (1937)

covered a filter-passing agent from a group of 200 *Dermacentor andersoni* ticks collected near Nine-Mile Creek about 32 miles west of Missoula, Montana, U. S. A. They described the reaction of guinea pigs to the infectious agent and found white mice and white rats to be susceptible. It was shown to survive in, and to be transmitted by, nymphal and adult *D. andersoni* that ingested the virus in the larval stage, and survived through the eggs deposited by infected females to be transmitted to the progeny. It was found to be a minute, Gram-negative pleomorphic rickettsia-like organism that occurred both intra- and extracellularly in the infected tissues of guinea pigs.

By a fortuitous circumstance, a member of the staff was accidentally infected and the human pathogenicity of the agent demonstrated. Moreover, the resemblance of this human infection to the new disease described by Derrick in Australia was recognized. "One way" cross immunity tests suggested that the infectious agent isolated in Montana and the causative agent in Q fever were closely related, or identical. A comparative study of the rickettsial strains from infected ticks in Montana and from Q fever was conducted by Burnet and Freeman (1939). It was concluded that the Montana strain belonged to the same species as *Rickettsia australis*.

During the spring of 1940, 15 cases of "pneumonitis" occurred among the 153 employees of one building of the National Institutes of Health (Hornibrook and Brown, 1940) in Washington, D. C. These 15 patients all showed roentgenographic evidence of pneumonic infiltration. In addition to these, there were a few others who had a similar but somewhat milder attack who either gave negative x-ray findings or in which roentgenograms were not obtained. Four attempts were made to isolate the causative agent from proved cases of pneumonitis. The identical agent was isolated in three of the four and later identified as the rickettsia of Q fever. No valid evidence was produced that personal contact or the intervention of an arthropod vector was responsible for the transmission of the disease. Two important inferences were drawn from this experience. The type of infiltration revealed by the x-ray, and certain other clinical characteristics of these cases, were similar to the syndrome termed "primary atypical pneumonia." From this time on, therefore, Q fever was included with the other pulmonary infections and a differential diagnosis of primary atypical pneumonia. The epidemiological study of the circumstances under which the outbreak occurred, led to the conclusion that these accidental laboratory infections were air-borne. It was notable, however, that there were no secondary infections among familial associates of the cases.

On the basis of these early observations, there followed a series of contributions which have shown that Q fever is an important human disease in localized areas of the world.

**Clinical Recognition.** Neither the history nor clinical course are sufficiently characteristic to establish a diagnosis. The incubation period ranges from 14 to 26 days, with a mean of 19 to 20 days. The onset is generally abrupt, with fever, chills, rigors, general weakness, malaise, headache, and muscular aches. Symptoms referable to the upper respiratory or gastro-intestinal tracts are inconspicuous. About the fifth or sixth day a mild dry cough develops in the majority of patients, and many complain of pain in the chest. Careful physical examination at this time may reveal the presence of a few rales and slight diminution of resonance. Evidence of pul-

monary involvement, indistinguishable from that of primary atypical pneumonia, is found by roentgenogram in practically all patients, even including those who are so mildly ill that they would not ordinarily seek medical care. The febrile period may last from 1 to 14 days, but in about half the patients the fever is of three to six days' duration. Convalescence is rapid. The disease is rarely fatal.

**Laboratory Diagnosis.** Confirmation of the diagnosis of Q fever by serologic means is accomplished either by the agglutination or complement-fixation technique. It is highly desirable that early and late specimens of sera be tested for antibodies in order to demonstrate the appearance of antibodies during convalescence or an increase in titer. Complement-fixing antibodies are detectable between the seventh and thirteenth day in practically all cases and rise steadily to a maximum titer, usually in the range of 1:160, which is reached about the twenty-first day (Robbins and others, 1946).

Isolation of *R. burneti* from the blood of patients during the febrile phase may be accomplished by guinea pig inoculation. The usual incubation period in the guinea pig, following intraperitoneal inoculation of 2 ml. of blood virus, is from four to six days, the extremes are 2 to 10 days. The temperature is continuous in most of these animals for from two to eight days, averaging between 40° and 50° C. The common febrile period is from two to four days. Certain strains regularly cause death in guinea pigs, even on inoculation of only a few infectious doses; others are lethal only when highly concentrated material is used for inoculation. All strains are readily adapted to growth in the yolk sac of chick embryos.

**The Etiologic Agent.** Because of its filtrability, Philip in 1943 expressed the individuality of the causative agent of Q fever by placing it in a separate subgenus *Coxiella*. It differs from the causative agents of typhus, spotted fever and tsutsugamushi disease in resistance to physical and chemical agents. *Coxiella burneti* is relatively resistant to desiccation. This quality, together with the fact that the feces of infected ticks are rich in viable organisms, is important in the transmission of the disease. Of similar significance is its resistance to heat. Although thermal death points as understood in bacteriological sense were not obtained, Q fever organisms were found by Ransom and Huebner (1951) to survive temperatures as high as 63° C when suspended in milk, sealed in vials and submerged at 30 to 40 minutes in water baths. Final concentrations of 0.5 per cent formalin failed to inactivate per cent yolk sac suspensions of *C. burneti* after 96 hours at 4° C but 1 per cent formalin was effective in 72 hours.

**Treatment.** Treatment with tetracycline antibiotics or chloramphenicol appears to be effective in suppressing symptoms. These drugs should be administered orally and continued for several days after the patient is afebrile. If relapse occurs treatment should be reinstated.

**Propagation and Transmission.** According to Derrick (1953) at least 10 species of ticks have been found naturally infected. They came from widely separated localities from four continents. Nine species have been found able to transmit *C. burneti* from host to host under experimental conditions. Multiplication takes place in the epithelial cells lining the gut, and the lumen contains numerous rickettsiae. Transovarial passage has been demonstrated in three species. Ticks and tick feces are the most concentrated natural sources of *C. burneti*. Apart from ticks, no other arthropod except the human louse has been found naturally infected.

Ticks provide a high titer geographically widespread reservoir of *C. burneti*. Their hosts assist them either by taking part in the tick-animal-tick cycle of transmission or, where transovarial passage occurs in the tick, simply as accessories necessary for nourishment.

The search for naturally infected animals and birds has resulted in the isolation of *C. burneti* from six species: cows, sheep, goats, bandicoot, merion and pigeon. The first three provide a notable source of infection for their environment, periodically and intensively contaminating the soil with placenta and postpartum discharges; more continuously at a low titer through milk.

Because of the high resistance of *C. burneti* to heat and desiccation, it can survive for comparatively long periods of time in soil, dust, contaminated hides, wool, etc. The conditions under which most of the human infections occur are consistent with the concept that in a majority of cases *C. burneti* are air-borne and the mode of entry is through the respiratory tract.

In the United States, natural infections have been demonstrated in *D. andersoni* in western Montana and Wyoming, and *D. occidentalis* in Oregon and California, *Ixodes americanus* in Texas, *Haemaphysalis leporis-palustris* in Virginia, and *Ixodes dentatus* in Virginia and New York (Kohls, 1948). Considering that the agent has been recovered from five species of ticks from widely scattered sections of the United States, and that three of these species commonly attack man, it is remarkable that as yet no human infections have been definitely traced to ticks or other arthropods.

During World War II, Q fever was found to occur endemically and epidemically in the Mediterranean countries of Italy, Corsica and Greece (Commission on Acute Respiratory Diseases, 1946). The evidence identified Q fever with "Balkan grippé" and the occurrence of outbreaks in Athens, Greece, in the winters of 1943-44 and 1944-45. During the winter of 1944-45 and the spring of 1945, seven outbreaks of the disease, initially diagnosed as atypical pneumonia, which occurred in American troops stationed in Corsica and the North Appennine region of Italy were investigated. The mode of transmission of the agent was not ascertained; the epidemiological evidence pointed toward an extrahuman source and possibly an intermediary vector.

When Q fever was discovered in the metropolitan area of Los Angeles in 1947, extensive epidemiological studies were undertaken by the National Institutes of Health with cooperation of the California State Department of Health and Agriculture and the Los Angeles City and County Health Departments. The results are being published in a series of reports. According to Bell and others (1950), Q fever has been occurring endemically in the Los Angeles area and it is highly probable that more than 50,000 persons have been infected with *C. burneti* in recent years. It appears that a considerable portion of these infections were manifested as an identified acute illness with fever for two or more days.

Early in the course of these studies, it was noted that proximity to dairies, by reason of occupation or residence, was a common factor in the histories of more than 50 per cent of the cases (Huebner and others, 1948). Except for dairy workers, it was noted that the infected persons rarely used milk from nearby dairies. It was found in fairly extensive serological surveys that 10 to 20 per cent of dairy workers in the Los Angeles area possessed serum antibodies for Q fever. Epidemiologic

studies showed that, of 60,000 cattle shipped into the area annually, between 40 and 50 per cent acquire asymptomatic infection within six months after being brought on the infected premises. These animals shed *C. burneti* continuously or intermittently in the milk for periods of time exceeding one lactation period. The organisms were isolated on autopsy from the mammary gland and adjacent lymph nodes of an infected cow. Dairy cows were shown to be sources of gross contamination of the environment by the post-parturient passage of highly infected placental membranes (Luoto and others, 1951). *Coxiella burneti*, the causative organism of Q fever, was recovered from raw milk from four widely separated dairies in Los Angeles County. Further studies showed the commercial pasteurization substantially reduced but did not entirely eliminate the infection from milk (Huebner and others, 1949). The organism survived 41 days in refrigerated butter made without pasteurization (Jellison and others, 1948). An epidemiological analysis showed that the human cases were rarely ever direct sources of infection for other persons, and that insects and arthropods played little if any role in the spread of the disease to human beings. The most frequent and by far the most important sources of human infection were local dairy cows, their very young calves, and some of their raw products, particularly raw milk and hides. Persons most likely to be infected were those who used raw milk in the household, those whose residence had been located near a dairy or livestock yard, those who had worked in industries handling live or recently killed dairy cows and young calves, e.g., employees in dairies and meat packing plants and fat rendering plants, employees handling the raw products of such animals, e.g., employees of creameries and hide plants. Human cases were found in association with infected herds of goats and sheep. In these animals the rickettsia leave the host not only in the milk and placenta but have been found in the feces and in wool tags and fleece of naturally infected sheep (Winn and others, 1953; Abinanti and others, 1955).

Further investigations by Lennette and others elicited the fact that Q fever was by no means limited to the Los Angeles area in California but was occurring in other localities of the state.

**Prevention.** The prevention of natural exposure to Q fever constitutes an unsolved problem. Fortunately, the risk is limited. While the primary cycle may involve small vertebrates and their tick ectoparasites, this source of infection appears to be of no consequence to man. Aside from the ingestion of contaminated raw foods, the principal medium of dissemination seems to be air-borne contaminated dusts. One obvious preventive measure is the proper pasteurization of milk of cows, goats and sheep. A vaccine has been produced that seems to be valuable for the protection of laboratory workers but is still in the stage of experimental development. Isolation of cases is unnecessary, since communicability from man to man has not been demonstrated.

# RICKETTSIALPOX

In 1946, an unusual febrile illness with varicelliform rash became epidemic in a New York City housing development. One hundred twenty-four cases were identified with the assistance of attending physicians and investigated by representatives of the New York City Health Department and the National Institutes of Health. The clinical features of this new disease have been fully described by Greenberg and others (1947a).

The onset of the disease is usually heralded by a primary papular skin lesion which undergoes vesiculation followed by the formation of a black eschar, which heals with scarring. The lesion may attain a diameter of 5 to 15 mm. and is usually distinctly larger than the lesions of the subsequent generalized eruption. Regional lymph nodes are usually enlarged and sometimes tender. Constitutional symptoms usually begin two to seven days after the appearance of the initial lesion. They include chills or chilly sensations, fever (the temperature ranging up to 104° F), headache, muscular pains and lassitude. The characteristic feature of the disease is the rash, which appears at any time from the first to the sixth day of the fever. It begins as erythematous maculopapules from 2 to 10 mm. in diameter. In from 48 to 72 hours, a variable proportion of these develop at the apex of the papule a small vesicle containing cloudy fluid. The vesicles usually give way to small crusts which heal without scarring. Lesions appear on the face, trunk, extremities, rarely on the palms and soles, and occasionally on the tongue, palate, buccal mucosa and pharynx. The eruption varies from very extensive to scanty, but lesions are found in more

than 90 per cent of cases. The fever, systemic symptoms and the eruption may last from 2 to 10 days. Leukopenia is more or less consistently present.

**Laboratory Diagnosis.** Etiological studies were begun by Huebner and his associates (Huebner, 1948) on July 25, 1946. During the following three months, nine identical strains of rickettsiae, subsequently named *Rickettsia akari*, were isolated: two from patients; six from rodent mites, *Allodermanyssus sanguineus*; and one from a wild house mouse, *Mus musculus*. In mice, a definite, sometimes lethal, illness was produced by this agent. *Rickettsia akari* inoculated intraperitoneally into guinea pigs produced a nonfatal disease similar to Fièvre Boutonneuse and endemic typhus. The incubation period of four or five days is usually followed by an irregular low grade fever of from one to four days' duration. A consistent sign of the disease in the male guinea pig is an inflammatory scrotal reaction. Growth on the yolk sac of fertile hen's eggs is prolific. Immunologically, *R. akari* is related to *Dermacentor troxenus conori*. The Weil-Felix reaction is negative with Proteus OX19, OX2 and OXK. The diagnosis of rickettsialpox may be confirmed by the development in convalescence of a high titer of complement-fixing antibodies in tests with antigens of *R. akari* (Greenberg, 1948).

**Transmission.** There is considerable evidence that rickettsialpox is transmitted to man through the agency of the rodent mite, *Allodermanyssus sanguineus* Hirst. The occurrence of an initial skin lesion in this disease, as in tsutsugamushi disease, is presumably the result of inoculation of the infectious material by a mite bite. The disease has a very limited focalized distribution. While multiple cases occur in a particular domicile, there is no evidence of spread by direct contact from person to person. Wherever a careful search has been made, house mice infested with *Allodermanyssus sanguineus* have been found in close proximity to the cases. Finally, strains of rickettsiae recovered from human sources, from pools of mites, and from the house mouse have been found to be identical by cross immunity and serological tests.

**Prevalence.** The epidemiology of the disease has been described by Greenberg and others (1947b). Investigations conducted in New York City revealed the fact that cases were occurring in five of the boroughs. Pike and others (1950) reported a serologically proved case occurring in a resident of Boston. It may be expected that the disease will be discovered in other communities, since *Allodermanyssus sanguineus* is known to occur in Indianapolis, Indiana; Tucson, Arizona; and the District of Columbia; and possibly in many other communities. Exposure to infection is associated with dwelling conditions which are favorable to harborage for mice. *Allodermanyssus sanguineus* is not uncommonly found attached to and feeding on the mice, the usual site of attachment being the rump. However, these mites wander some distance from mouse nests to adjoining walls and floors. Obviously, the prevention is a matter of suppression of mouse infestation on domestic and occupational premises.

### TRENCH FEVER

(*Five Day Fever, Wolhynian Fever*)

During the early period of World War I, a hitherto unknown mild disease characterized by febrile relapses became widely prevalent in some of the armies in northern Europe. McNee and others (1916) described the clinical syndrome under the name of trench fever. Typically, the onset was sudden, accompanied by headache, dizziness, pain in the legs, especially the shins, injection of the conjunctivae and a sharp rise in temperature. Usually the fever subsequently assumed an relapsing character. In a majority of cases, an eruption of small erythematous macules or papules appeared, scattered principally over the chest, back and abdomen. The eruption appeared as early as the second day of fever or was observed prior to or during a relapse. It often disappeared within 24 hours. There were many variations in the clinical course. From three to five relapses were common and in some cases had six or seven. Sometimes relapse occurred after several months of quiescence. Complete recovery was the rule; the disease was almost never fatal. Because of an obvious association with military personnel in the front lines, it was called "trench fever." The term Wolhynian fever was applied to it because the supposed source of the infection was in that area. It was called "five day fever" because of the interval between relapses. Whichever name was used, it became evident that it was one of the most important causes of manpower loss in the fighting armies. During 1917-18, before the influenza epidemic, it was the cause of from one fifth to one third of all cases of illness in the British armies in France. Two commissions were set up—the British Trench Fever Commission and the American Red Cross Commission—to investigate the cause, pathogenesis, mode of transmission and prevention. Their findings have been summarized by Swift (1920).

According to this early work, the many clinical forms of the disease are apparently not due to different types of the causative agent, but to single or multiple infections of a single type. The intensity and duration of an attack seemed to depend on the balance between dose and the virulence of the infecting micro-organism and development of immunity by the human host. Attempts to recover the agent from the blood of patients by the inoculation of artificial media tissue culture or chick embryos were unsuccessful. Small laboratory animals were not susceptible. Recently, it has been demonstrated that a reaction and characteristic febrile relapsing course could be produced in the baboon and in the *Macacus rhesus* monkey (Looser and Weyer, 1953a, b).

In the early work it was necessary to resort to the inoculation of human volunteers.

Under suitable conditions, the agent could be passed through a Berkefeld filter, but the results were irregular. The agent was found occasionally in the sputum of patients, often in the urine, and always in the blood at some stage. Experimentally it was transferred from man to man by intravenous or intramuscular injections. The incubation period varied from 5 to 20 days. After an interval of from 5 to 10 days

following the infecting feed it was found in the excrement and bodies of lice (*P. humanus*) that had fed several times on trench fever patients. When a louse had started to excrete the agent, it continued to do so for the remainder of its life. It was not passed from one generation of lice to the next through eggs.

The life span of the infected arthropod host is not materially shortened. There was remarkable correspondence in the infectivity of louse excrement and the time of appearance of rickettsia-like micro-organisms. They were observed on the surface of epithelial cells lining the gut, and free in the lumen, apparently multiplying extracellularly. Evidence supports the concept that they are the causative agents of trench fever. They have been classified as *Rickettsia quintana* by Schmincke in 1917 (syn. *R. wolhynica*, *R. pediculae*) (Mooser and others, 1948).

Man appears to be the reservoir host for *R. quintana*. Where it multiplies in the body, whether in the blood or in the organ tissues, is not known. After infection of the human host it circulates in the blood stream for a variable time—from a few days to months—with or without clinical symptoms. After months, even after years of latency, relapse or recrudescence may occur. Its alternate host is the human louse, which may harbor *R. quintana* for a few weeks at most. Its survival requires an ecology which is favorable to man-to-man transmission by lice.

A critical study to determine the effective use of antibiotics in treatment has not been made. As with epidemic typhus, control or eradication of the disease follows upon measures designed to reduce lousiness. In World War II, trench fever was of little or no importance as a cause of morbidity in the military forces. Knowledge of its prevalence among civil populations is fragmentary.

## CONTROL OF ARTHROPOD VECTORS AND INFESTATIONS

LLOYD E. ROZEBOOM, Sc.D.

Medical entomology deals with the arthropods which cause or carry human diseases. The concept of disease transmission through arthropods developed especially during the latter part of the nineteenth century, through the thinking of men like Nott, Beauperthuy, Finlay, and King, who, from various epidemiological observations, reasoned that malaria and yellow fever could be caused by mosquito attack. Meanwhile sounder evidence was accumulating through the experiments of Henshaw, Fedtschenko, and Melnikoff on the transmission of the filaroid worms, *Brugia malayi* and *Dracunculus*, through Cyclops and of the dog tapeworm through dog fleas and fleas. The greatest impetus to this line of thinking was furnished by Manson's demonstration in 1878 that the filaria worm, *Wuchereria bancrofti*, underwent a definite developmental cycle within the body of a mosquito, *Culex fatigans*. In 1894-95, Bruce showed that the tsetse fly was responsible for Nagana in Africa; in 1889, Smith and Kilbourne proved the role of the tick as a vector of Texas fever of cattle; this was followed by the discoveries of the role of mosquitoes in the transmission of malaria by Ross in 1897-98 and yellow fever by Reed in 1900. Since then the importance of the role played by arthropods in the epidemiology of human and animal diseases has been made abundantly clear, and it is recognized that knowledge of the taxonomy and biology of the vectors is essential to a proper understanding of the epidemiology and control of the arthropod-borne diseases. The Phylum Arthropoda is divided into several classes, two of which contain bloodsucking species that are of importance as disease vectors. The class *Insecta* (Hexapoda) comprises the insects, which are recognized by their external, shell-like skeleton, segmented body, and jointed legs and antennae. The insect body is divided into a head, a leg- and wing-bearing thorax, and an abdomen. Usually, there are two pairs of wings; but among the medically important forms, the flies have the second pair of wings reduced to small balancers or halteres, while the lice, fleas, and bedbugs, through parasitism, have lost all vestige of wings. The bloodsucking insects are found in four systematic divisions called Orders. These are the *Diptera*, or flies; the *Siphonaptera*, or fleas; the *Anoplura*, or lice; and the *Hemiptera*, or bugs. The class *Arachnida* includes the ticks, mites, and spiders, as well as other forms such as crabs and lobsters of no medical importance. The *Arachnida* differ from insects especially in that the body is divided into two regions, the cephalothorax and abdomen; there are eight pairs of legs in the adult, and wings and antennae are lacking.

Two other classes of arthropods which must be noted are the *Scorpionida*, or scorpions, possessing a poisonous sting at the tip of the tail-like terminal portion of the abdomen, and the class *Chilopoda*, the centipedes, which have the front pair of legs modified to form poisonous claws.

The insects, in their development from egg to adult, undergo a remarkable series of transformations, a process which is called "metamorphosis." There are several types of metamorphosis, depending upon the phylogenetic position of the insect. The primitive wingless silverfish and bristletails are ametabolous, that is, they undergo no marked changes. The ametabolous development of the highly specialized lice is due in part to the loss of the wings through parasitism. The insects which undergo a gradual metamorphosis have young which resemble the adult insect except that the wings are small and develop gradually in external pads. The young of these insects are called nymphs. In incomplete metamorphosis the legs and wings develop externally, but the immature stages, called naiads, are adapted for an aquatic existence, while the adults are aerial. Comstock says the naiads are "sidewise developed." May flies and dragon flies are examples of this type of metamorphosis. In complete metamorphosis the developmental stages are the egg, the larva, the pupa, and the adult. In the worm-like larva, the legs and wings develop internally. The pupa is a so-called resting stage; within the pupa the larval tissues are broken down and transformed into those of the adult.

#### THE ROLE OF ARTHROPODS IN MEDICINE

The role of arthropods in medicine is that of being directly responsible for pathological conditions in man and animals, or they may act as carriers of disease agents. Under the former are included hypersensitivity to insect bites or stings; allergic responses to scales and hairs from wings and bodies of butterflies, moths, and other insects; and direct invasion of the body by mites and parasitic fly larvae.

In transmitting pathogenic organisms, arthropods may be simple mechanical vectors, or they may be biological hosts for pathogens whose existence depends upon completing part of the life cycle within the body of the arthropod. Typhoid bacilli, yaws spirochetes, and other organisms which are present in the discharges and exudates of the diseased body may be carried mechanically by flies or other insects directly to a new victim or to food and drink about to be ingested. Arthropods are biological hosts for viruses, bacteria, spirochetes, protozoa, and helminths. Within the body of the vector the viruses, bacteria, and possibly the spirochetes undergo a simple multiplication; this is called the *propagative* type of development. The protozoa and helminths undergo part of their life cycle within the arthropod, they are transmitted biologically, and when there is no multiplication of the parasite the transmission is said to be *cyclodevelopmental*; when there is multiplication as well as a biological cycle, the parasite-vector relationship is called *cyclopropagative*. The host in which the sexual stages of the parasite occur is the *definitive* host; the asexual stages occur in the *intermediate* host. Thus man, and not the mosquito, is the intermediate host for the malaria parasites, while mosquitoes are intermediate hosts for the filarial worms. A certain length of time is necessary for the development of the parasite within the arthropod to the point where it can be transmitted biologically by the bite or dejecta of the vector; this is termed the *extrinsic incubation period*. Within mechanical transmission there is no incubation period. Hereditary trans-

ion refers to the ability of ticks and some of the mites to pass the disease organisms through the eggs to the succeeding generations; none of the insects can do this, although it has been claimed that the virus of pappataci fever can be passed ovarially through *Phlebotomus*.

### THE CONTROL OF ARTHROPODS OF MEDICAL IMPORTANCE

The epidemiology of the arthropod-borne diseases may be represented as being the links of a chain; the two end links, the patient (or animal reservoir host) and the uninfected person, are connected by the middle link, the arthropod vector. The vector is indispensable for the successful passage of the disease agent from the sick to the well. The whole purpose of control of the arthropod-borne diseases is to break the links of the chain, and one may separate the procedures for bringing this about into measures of a defensive nature or as measures of attack. Measures of defense include the use of protective clothing and repellents to discourage insect attack; the avoidance of those places in which there is danger of being bitten by infected insects, such as swamps and villages in which malaria mosquitoes become active at night, or tsetse-infested bush; and the use of bed nets and screens. These measures are usually applicable to individuals and relatively small groups of people who find themselves in an endemic area, but sometimes may be employed to great advantage in protecting communities or armies. Widespread use of repellents undoubtedly played a considerable role in prevention of malaria and scrub typhus among military personnel operating in the Pacific areas during World War II.

The older *repellents* such as oil of citronella or pennyroyal have fallen into disuse because of the far more effective compounds discovered during World War II. The repellents which have been used most widely are dimethyl phthalate, dimethyl pivalate, Indalone (n-butyl mesityl oxide oxalate), and Rutgers 612 (2-ethyl-1,3-bis(2-methyl-2-propenyl)-1,3-propanediol). A mixture of 6 parts dimethyl phthalate and 2 parts each of Indalone and Rutgers 612 is known as 6-2-2 and is effective against a greater number of arthropods than is any one of the ingredients. In general, these repellents will protect for two or more hours, even when the user is sweating heavily. They may be sprayed over the skin of the exposed parts of the body; they may be rubbed onto clothing by hand; or clothing may be impregnated through the use of solutions or emulsions. Care must be taken not to get them into the eyes; and as they are solvents for paints, varnishes, and plastics they will damage watch crystals and other objects made of plastics, synthetic clothes, and similar products. Repellency is a complicated phenomenon, and the mode of action is not yet well understood. A compound may repel one species but not another. More effective materials are being sought.

In Africa, large communities have been protected from sleeping sickness through the use of insecticides in areas where tsetse flies do not exist. Such measures do not reduce the vector density, but are effective in breaking the transmission chain through the prevention of contact of the vector with the source of infection or the potential host. The use of prophylactic drugs may also be thought of as being a defense measure.

The measures of attack are designed to destroy the middle link of the chain by greatly reducing or even exterminating the vector population. These may be divided into several categories, as given below.

**Naturalistic Control.** Animal populations are held in check through the forces of nature, such as the topography of the country, nature of the soil, climate, types of vegetation, availability of food, and the activities of predators and parasites. When these natural forces are unbalanced outbreaks of insects may occur. The replacement of indigenous flora with vast cultivated crops has favored certain species which have become agricultural pests; introduction of insects into new regions where their normal predators and parasites are absent may permit them to build up tremendous populations; and creation of artificial breeding places for mosquitoes through alteration of the topography by man may give an anopheline species the opportunity to multiply to the point where it becomes a health hazard. One might say, therefore, that natural measures are the most effective in keeping arthropods in control, and by naturalistic control we mean the conscious imitation of these natural forces by man. Its application requires an intimate knowledge of the life history and ecology of the arthropod. These measures may be very simple and economical, or they may be complex and involve huge and expensive engineering projects. But whether simple or complex, naturalistic control is the most effective measure because the environment is altered, more or less permanently, to make it completely unsuitable for the existence of the arthropod against which the work is directed. Not all naturalistic measures require engineering technics, but all engineering methods have as their objective the bringing about of natural control. Drainage, filling, the damming and flushing of streams, proper sewage disposal, sanitary garbage fills, and the like, whether planned directly for arthropod control or not, are all naturalistic measures which reduce or eliminate disease vector populations. Environmental sanitation may have a high initial cost, but has the advantage over other methods of control in that it is more effective and is not repetitive. The cost of maintaining the altered environment is usually small.

**Mechanical Control.** Under this heading we may include various mechanical devices which destroy insects. Hand catching of mosquitoes with a net or chloroform tube will destroy only a few individuals, but nevertheless, if practiced in an area where disease vectors enter houses, it may prevent transmission of diseases by regularly destroying infected individuals. Hand picking of ticks from the body, after exposure to them in their habitat, is an effective means of preventing the inoculation of rickettsial pathogens. Hand catching of tsetse flies by organized teams of fly boys has greatly reduced or even eradicated the flies and sleeping sickness from certain places in Africa.

Many types of traps have been designed to capture and destroy insects. Traps are valuable for determining the density of insect populations, and hence for showing the effectiveness of control campaigns. The New Jersey light trap is equipped with a fan which sucks insects, attracted by the light from a distance, into the trap where they are overcome by HCN fumes and fall into the killing jar at the bottom. These traps are especially effective in catching mosquitoes, and have been used widely in surveys and in control operations. Mosquito abatement organizations set an arbitrary low nightly mosquito count as their goal; when the count rises beyond this number it is realized that control procedures are not adequate. Stable traps which consist of screened sheds containing an animal such as a calf or horse as bait, will catch thousands of mosquitoes in one night if placed properly. The insects enter the trap through slits in the sides, or the door of the trap may simply be left

in during the night and closed early the following morning. The animal is retained by being placed in a properly constructed stall. Although traps may catch great numbers of mosquitoes and other insects, it must be remembered that the flies represent only a small proportion of the total adult population, and that as the reproductive potential of insects is extremely high, the uncaught adults will produce more eggs than are necessary for maintaining the population at normal density. Fly traps, sticky papers, and the like, may alleviate annoyance by reducing numbers of free-flying individuals in a restricted locality, but they do not reduce general fly density. Perhaps the most successful use of traps has been in tsetse control campaigns.

**Chemical Control.** The use of insecticides is often the only manner in which an arthropod can be attacked. Insecticides have the advantage of being immediately effective in destroying the disease vector, but they are expensive and must be used judiciously. During World War II, powerful new insecticides were discovered, and it was hoped that if used correctly over a sufficient length of time, some of them will eventually bring about extermination of certain disease vectors. There are three types of insecticides: stomach poisons, fumigants, and contact poisons.

*Stomach poisons* must be ingested in order to kill, and so can be used only against those insects which have chewing mouth parts. Such insects, armed with mandibles and maxillae, bite off parts of leaves or other food, and the poison may be spread over the natural food or it may be incorporated in an attracting bait. Stomach poisons are used widely in agriculture, as many of the insects attacking crops have chewing mouth parts. Insecticides used as stomach poisons are the cyanides, cryolites, phenothiazine, hellebore, phosphorus, thallium sulphate, and borax. Stomach poisons have little use in control of medically important arthropods, for most of these parasites have piercing-sucking mouth parts adapted for acquiring blood from their hosts. Up to the time DDT became available, Paris green was used widely as an anopheline larvicide. These larvae feed upon small particles lying in the surface film, and particles of Paris green are ingested with the food. The poison was distributed as a dust in an inert carrier at the rate of 1 pound of the Paris green to 1 acre of water. Phenothiazine has been shown to be highly toxic to mosquito larvae; hellebore and borax have been used to kill fly larvae in manure, and formaldehyde can be used as a poison in a sweet liquid to kill flies.

*Fumigants* are taken into the respiratory tract and so will kill regardless of the type of mouth parts possessed by the arthropods. They are valuable for control in grain storage bins, warehouses, greenhouses, and the like, where the insects cannot be reached by ordinary sprays or dusts, or where such insecticides might harm the material being infested. Since the development of the new residual insecticides, it is no longer necessary to resort to fumigants to solve most control problems involving insects of medical importance. They are still used extensively for extermination of rats in holds of ships; the object of this is rat rather than insect control (see Chapter 8). There is no question as to the effectiveness of fumigants; a house infested with bedbugs will be freed not only of these pests but of all other living creatures as well through adequate fumigation. But the elaborate preparations necessary, the expense, and the danger to occupants of the premises would make it preferable to select another method, especially since the newer insecticides will give results that are as good, or nearly so, as those obtained with fumigants.

*Hydrocyanic acid* (HCN) has been used very extensively as an insect fumigant. The gas may be generated by adding sodium cyanide to sulphuric or hydrochloric acid, or from liquid hydrocyanic acid stored in heavy steel cylinders, but usually the most convenient method is to use dry preparations. These are finely powdered calcium cyanide, or Fuller's earth or paper discs impregnated with liquid HCN. HCN fumigation should be carried out only by experienced operators.

*Sulphur* has been used as an insecticide in several forms. The gas  $\text{SO}_2$  may be produced by burning sulphur or by liberating liquefied sulphur dioxide. It is cheap, readily procurable, and it will kill household insects, but its disadvantages are that it tarnishes metals, rots fabrics, and bleaches pigments. Flowers of sulphur ointment and sulphur-impregnated soaps are effective for treatment of scabies, but may produce dermatitis; lime and sulphur dips have been widely used to destroy mites on domestic animals.

*Disulphide of carbon* ( $\text{CS}_2$ ) is an efficient insecticide, but a dangerous one, on account of its inflammable and explosive nature; every precaution must be taken to see that there is no fire, lighted cigar, etc., in or about the field of operation. The gas is heavy and has good powers of penetration; therefore, it is useful for destroying insects in grain storage bins, in clothing, furniture, and for insects which burrow into the ground or wood. It is used to kill bot larvae in the stomach of horses. It was extensively used in California in the plague campaign. A piece of waste the size of an orange was saturated with the liquid and the wet ball placed in the mouth of the squirrel hole. Wet clay was then stamped into the warren so that the gas would have no opportunity to escape. The gas kills not only the squirrels, but also the fleas on them.

*Carbon tetrachloride* ( $\text{CCl}_4$ ) may be used in place of carbon disulphide. It is neither inflammable nor explosive.

*Methyl bromide* ( $\text{CH}_3\text{Br}$ ) is used to combat various economic pests and also for fumigation of rodent burrows.

*Chloropicrin* ( $\text{CCl}_3\text{NO}_2$ ) may be used for household fumigation, and has the advantage of being extremely irritating and hence safer to use than other fumigants. The use of chloropicrin discoids as a warning prior to HCN fumigation of ships has saved several lives.

Other fumigants which have been used for household pests are ethylene dichloride ( $\text{CH}_2\text{Cl}.\text{CH}_2\text{Cl}$ ); ethylene oxide ( $\text{C}_2\text{H}_4\text{O}$ ), and naphthalene ( $\text{C}_{10}\text{H}_8$ ).

The most useful of the compounds used in public health insect control are the *contact insecticides*, which kill regardless of the type of mouth parts possessed by the arthropods. The important ones are listed below.

*Pyrethrum* is obtained from the dried flowers and buds of *Chrysanthemum cinerariaefolium*, *C. rosei*, and *C. marshalli*. Formerly it was used only as a powder and the lukewarm discussion of pyrethrum in earlier editions of this book were probably due to the relative ineffectiveness of the unstandardized powders and fumes produced by burning the powder with alcohol. The extraction of pyrethrum with kerosene and the chemical analysis of the insecticidal principle has made it possible to standardize the product sold commercially. The active material in pyrethrum was first thought to be two esters which were named "Pyrethrin I" and "Pyrethrin II." These, however, have proved to be mixtures, and Frear (1948) points out that more work is necessary to determine the nature of the substances

are designated as Pyrethrin I and II, and Cinerin I and II. These materials are stable, and decompose in the presence of light, air, and moisture. The freshly prepared extract should be purchased, and it should be stored in dark, tightly closed containers.

For routine use, pyrethrum may be purchased from the manufacturer as a 1 per cent concentrate; this represents the use of 20 pounds of flowers to make one gallon extract, and the extract is standardized to contain 2 gm. of pyrethrins in 100 ml. For ordinary use one part of the extract is diluted with 19 parts of kerosene (or other light petroleum oil) to make a 5 per cent solution; the final product, therefore, contains 0.1 gm. of the esters per 100 ml. of spray. This spray is highly effective against common household pests, but if applied too lightly, houseflies and other insects may recover after having been knocked down. The rapid paralyzing effect of pyrethrum is highly desirable in household space sprays. Another advantage is its harmlessness to man and domestic animals when used as an insecticidal spray. Disadvantages are the ability of insects to overcome the effects of too small doses, and its instability. These may be overcome in part by combining pyrethrum with one of the new slow but sure insecticides such as DDT, by the addition of synergists to increase the toxicity of pyrethrum, and by the use of antioxidants to delay decomposition.

Pyrethrum synergists include isobutylundecylenamide and sesamin. The latter was an ingredient in the earlier aerosol formulations, but it was found later that kerosene and mineral oils were just as effective. For control of arthropods of medical importance, the combination of piperonyl butoxide with pyrethrum seems to be especially promising. This material is marketed under the trade name of Pyrenone, and may be utilized as a solution, dust, dispersable powder, or aerosol. The piperonyl butoxide greatly increases the knock down and kill, and delays the deterioration of pyrethrins so that Pyrenone may also be of some value as a residual insecticide. The principal advantage of Pyrenone is that it may be used safely in food handling establishments and in other situations in which the use of the chlorinated hydrocarbons represents a distinct hazard.

Recently Schechter and others (1949) have synthesized esters of the cinerin I component of pyrethrum. This material, called allethrin, is only one of the four insecticidal esters in pyrethrum, but it appears to be about as effective against houseflies as is pyrethrum. The synthesis promises to have commercial possibilities at a cost lower than that of extraction of natural pyrethrins.

**Thiocyanates.** The thiocyanates possess insecticidal properties, and two which have been used as substitutes for pyrethrum are beta-butoxy-beta'-thiocyanodiethyl ether, and isobornyl thiocynoacetate. A trade name for the former is Lethane, and for the latter, Thanite. These may also be combined with DDT or another of the chlorinated insecticides; this will ensure rapid knock down and high kill.

**DDT.** The name DDT is a contraction of dichloro-diphenyl-trichloroethane. This material was first synthesized by Zeidler in 1874, but it was not until about the beginning of World War II that its insecticidal properties were discovered. The Sandoz Company of Switzerland showed that it was toxic to certain household and agricultural insects, and in 1942 the U. S. Department of Agriculture began its investigations which demonstrated its effectiveness in combating insects of medical importance. During the war DDT was used extensively for the control of mosquitoes,

flies, and lice in military establishments. The great advantages of DDT over other insecticides are its extreme toxicity to arthropods but apparent relative harmlessness to man and animals, and its stability, which permits it to kill arthropods for months after having been applied to a surface upon which the creatures will alight.

DDT is a white crystalline material. The technical grade contains from 70 to 77 per cent of the p,p' isomer, which is the most insecticidal of the isomers formed in the manufacture of the compound. The aerosol grade contains 97 per cent or more of the p,p' isomer; a pure grade may also be obtained. It is insoluble in water. Its solubility in solvents commonly used in insecticidal preparations is as follows:

SOLVENT	Gm. DDT/ 100 ML.
Kerosene, crude . . . . .	8-10
Kerosene, refined . . . . .	4
Fuel oil, No. 1 . . . . .	8-10
Fuel oil, No. 2 . . . . .	7-10
Xylene . . . . .	53
Acetone . . . . .	58
Cyclohexanone . . . . .	116

In public health work, DDT is used most commonly as a 5 per cent solution in kerosene or fuel oil. Cyclohexanone is used as an auxiliary solvent for DDT in the Freon aerosol formulations.

Emulsions are made by addition of a suitable emulsifying agent to a solution of DDT. A standard formula is as follows:

DDT . . . . .	25 gm.
Triton X-100 . . . . .	10 ml.
Xylene . . . . .	65 ml.
Water . . . . .	425 ml.

Dissolve the DDT in the xylene, add the emulsifier, and then add water to make 500 ml. of liquid containing 25 gm. of DDT. The final product is, therefore, a 5 per cent emulsion. Various modifications of this formula have been used. With suitable water, the amount of emulsifier may be reduced considerably.

Suspensions of DDT are made by mixing DDT-coated or impregnated diluents, plus a wetting agent, with water. "Wettable powders" of various strengths are available commercially. Advantages of the suspensions are that they have a longer residual effect, and are safer to use on plants and animals, as there is no oil solvent present for the DDT. The wettable powders are finding wide use as dips and sprays for domestic animals. A disadvantage of suspensions is that sediment tends to clog the sprayers.

Dusts containing 10 per cent DDT in pyrophyllite or talc have had their greatest public health use as louse powders.

DDT gains entrance to the body of the insect through the integument. Chitin, an important constituent of the arthropod cuticle, absorbs DDT readily; it has been suggested that penetration occurs through the sensory organs and intersegmental membranes. The mode of action is not yet clearly understood. A recent review of the subject is that of Metcalf (1948). Within a few minutes after contact with DDT the insect shows signs of nervousness; it then becomes hyperactive and soon its movements lack coordination and are accompanied by rapid tremors, so that the

walking become erratic; finally it is unable to move except for isolated and nishing twitching of the appendages. Death ensues gradually.

Common with most insecticides, DDT is poisonous to man, but there is a wide margin of safety if it is handled sensibly. Several fatal cases of DDT poisoning in have been reported, but it seems to be uncertain whether the DDT or the ents were at fault. The dangerous acute and chronic doses for man are not as yet n. DDT dust may be used safely on the skin and clothing, but DDT may be rbed through the skin in solvents. Ingestion of large quantities will produce symptoms. DDT has been shown to accumulate in the fatty tissues of animals, small amounts ingested with milk may accumulate to dangerous levels. When are sprayed with DDT, or their food is contaminated with it, small amounts are ted in the milk. The Food and Drug Administration has ruled, therefore, that is a contaminant, and so this insecticide cannot be used on dairy animals, in y barns, milk sheds, and the like, or on crops destined to be fed to dairy animals. DDD. DDD or TDE, 1,1-bis(*p*-chlorophenyl)-2,2-dichloroethane, or dichloro- enyl-dichloroethane is very similar to DDT. It is less toxic than DDT to fish, so is safer to use as a larvicide, but it is also less effective in general against ts of public health importance.

*Methoxychlor*. This compound, 2,2-bis(*p*-methoxyphenyl)-1,1,1-trichloro- ne, is another analog of DDT, which may be used against household and other ts, but it is not as effective as DDT. It is not as toxic as DDT to man and estic animals, and so has been approved for fly control in dairy barns and on y animals.

*Benzene Hexachloride*. Benzene hexachloride (gammexane, 666, BHC) is 1,2,3,4,5,6-hexachlorocyclohexane. In the manufacture of BHC several space ers are formed, of which the gamma isomer is the most insecticidal. The techni- grades available commercially contain from 12 to 90 per cent gamma isomer. urified grade may also be obtained, containing at least 99 per cent gamma er; this has been named Lindane. Benzene hexachloride is another insecticide was developed during World War II, but has not been used as extensively as . The technical grade has an objectionable musty odor, which limits its use in es. It may be used as a solution, emulsion, wettable powder, or dust. It is highly to arthropods and acts more rapidly than does DDT. It also affects the nervous m, causing increasing excitement, tremors, ataxia and convulsions. It is more ile than DDT and hence does not have as long a residual effect. It is rather toxic an and animals, and so should not be allowed to contaminate food. It is not mended for use on dairy animals. It is effective in sprays, dips, and washes for ontrol of ticks, but because the margin of safety between the concentration for ment and that which is toxic to animals is small, it must be used on animals care. The halogenated compounds must not be used on animals in combination arsenicals.

*Lindane*. The purified gamma isomer of benzene hexachloride can be used in n smaller concentrations, and is recommended for use in dairy barns at the rate 5 mg. per square foot. It should not be allowed to contaminate foods and it is ecommended for use on dairy animals.

*Chlordane*. Chlordane (Chlordan, Octa-Klor, 1068) is 1,2,3,4,5,6,7,8,8- chloro-3a,4,7,7a-tetrahydro-4,7-methanoindane. This is a dark, viscous liquid,

and may be used as a solution, emulsion, wettable powder, or dust. It is highly toxic to arthropods, but it does not have as long a residual effect as does DDT. It has found wide use in control of flies, and at present is the insecticide of choice for combating cockroaches. The U. S. Public Health Service recommends a 2.5 per cent emulsion as a residual spray in certain portions of houses, such as baseboards and around windows and doors. It must be used with caution as it is quite toxic to man and animals. Its margin of safety is too small to recommend its use on animals; it should not be used in dairy barns, nor should it be used where there is danger of contaminating foods.

*Dieldrin* ( $C_{12}H_6Cl_6O$ ) is one of the newer compounds that has been used extensively in the control of medically important insects. It is effective against adult mosquitoes if applied as a residual spray in houses at a rate of 25 mg. per square foot. It is highly toxic to other household pests, and it may also be used as a fly or mosquito larvicide. Because of its toxicity, it should not be used in dairy barns or on animals and must not be allowed to contaminate foods.

*Toxaphene* ( $C_{10}H_{10}Cl_8$ ) is toxic to arthropods, but in general it is less effective than DDT and so has not found wide usage in control of insects of public health importance.

Other compounds are being developed for use against public health pests, especially for the control of DDT-resistant flies and mosquito larvae. Some are extremely toxic to man and should be handled only by experienced operators. *Parathion*-impregnated cords, hung in suitable locations, have been effective against house flies. *Malathion* has been used in sugar or molasses baits for control of flies in barns. Under certain circumstances, the following insecticides may be employed against the public health pests: *EPN*, *Dilan*, *Dipterex*, *Diazinon*, *Heptachlor*, and *Aldrin*.

**Application of the Contact Insecticides.** The contact insecticides are used as larvicides in the breeding habitat of mosquitoes and other *Diptera*; they are incorporated in powders, ointments, and other preparations for treating the hair, skin, and clothing of man against externally parasitic arthropods; and they are used for the control of adult insects in the form of space sprays and residual sprays. Each method of application requires certain techniques, some of which will be described later; the purpose of the present section is to consider the use of space sprays and residual sprays for the control of adult mosquitoes, flies, and other household insects.

Space sprays consist of insecticidal solutions which are dispersed as finely atomized droplets by means of any of a number of spraying devices available on the market. The spray gun may be the hand-operated, pumping atomizer familiar to every householder or gardener, the knapsack sprayer, or the paint-sprayer type attached to a motor-driven source of pressure. The spray is directed at the flying insects or at the spot where they are resting. To bring about a kill, the insects must be hit with the spray.

Any of the contact insecticides listed above may be used in solution as a space spray. The chlorinated hydrocarbons will insure a high kill, but they act slowly, and it is often objectionable, for example, to have DDT-poisoned flies making erratic flights about and into food about to be consumed. To overcome this, pyrethrum or another knockdown agent may be combined with about a 1 per cent solution of DDT or similar insecticide. Federal specifications require a minimum of 0.13 gram of Pyrethrin I plus the accompanying Pyrethrin II in 100 ml. of insecticide. Knockdowns comparable to that obtained with this amount of pyrethrum

be obtained with a 2 to 5 per cent solution of thanite or lethane. The use of ergists will permit the use of smaller amounts of pyrethrum. The pyrenones cause a rapid knockdown and a high rate of kill.

A modification of the space spray is the *aerosol*. Insecticides may be dispersed being vaporized through heating in the presence of a smoke produced by burning combustible material. In 1941 Sullivan, Goodhue, and Fales showed that flies could be killed by vaporizing naphthalene on a hot plate immediately after corn cobs and sodium nitrate had been burned in an open plate. Thermal aerosols are employed for treatment of large out-of-doors areas, and are produced by specially constructed machines which utilize super heated steam or a hot air blast to break up emulsions, emulsions, or suspensions into particles of aerosol dimensions; or by air-sprayers equipped with an extension of the exhaust stack into which the insecticide is pumped and converted into a fine spray and aerosol by the heat and blast of the exhaust. For indoor use, Sullivan and his associates (1942) developed the liquefied aerosol, which consists of a solution of the insecticide in dichloro-difluoromethane or similar material which forms a gas at ordinary room temperature. The chilled, liquefied material containing the dissolved insecticide is placed in a small container or "bomb" equipped with a suitable nozzle. Opening of the nozzle releases the gas, carrying the insecticide with it, drifts into space and eventually contacts all exposed insects within the enclosed space. Very small amounts of the aerosol are needed. These self-propelled aerosols are most convenient for temporary control of household insects. During the World War II aerosol "bombs" were employed as an antimalarial measure to kill mosquitoes in barracks, tents, and other living and sleeping quarters of military personnel. They are used for treatment of airplanes before and immediately after landings to prevent the introduction of exotic disease vectors and pests.

Many formulations of aerosols have been tried. The earliest aerosols used by the armed forces during World War I contained 1 per cent pyrethrins and a small amount of sesame oil as an activator. Later DDT was used as the killing agent, but a small amount of pyrethrum was retained because of its knockdown properties. It has also been shown that either vegetable or mineral oils could be substituted effectively for the sesame oil. Sample formulae are as follows:

FORMULA G-382

Pyrethrum (20% pyrethrins)	5 per cent
DDT	3 " "
Cyclohexanone (auxiliary solvent)	5 " "
Lubricating oil S.A.F. 30	2 " "
Freon 12	85 " "

FORMULA G-651

Pyrethrum (20% pyrethrins)	6 per cent
DDT	2 " "
Alkylated naphthalene (PD 544 or Velsicol AR-60)	8 " "
Freon 12	84 " "

From 3 to 5 gm. of total aerosol are used per 1,000 cubic feet of space. The use of residual sprays is a recent wartime development and represents an extremely important advance in the use of insecticides for the control of arthropod-

borne diseases. Residual sprays were made possible by the discovery of DDT and similar insecticides which are toxic in minute quantities and have long lasting properties. Instead of being directed at the arthropod, the residual spray is placed on some surface upon which the arthropod will walk or rest. Thus, instead of the necessity of spraying at weekly, biweekly, or even daily intervals to kill a few mosquitoes which happen to be within a house at the time the spraying is done, a single application of a residual spray on the walls of the house will kill for a three- or four-month period almost every mosquito (and other insects as well) that comes into the house.

From Stierli, Simmons, and Tazewell, Pub. Health Rep. Supp. No. 186, Fig. 4. 12

Fig. 7-1. Spraying a house with DDT emulsion.

This has been the most important single development in malaria control in recent years; it is now possible to bring malaria rates down to extremely low levels, and apparently even to eradicate the disease in rural tropical areas where formerly mosquito control measures were impracticable.

DDT and the other halogenated hydrocarbons are usually applied as residual sprays at the rate of 100 or 200 mg. per square foot of surface. Lindane, the gamma isomer of benzene hexachloride, is said to be effective at 25 mg. per square foot. Several years of experience has shown that for routine use against *Anopheles quadrimaculatus* in the southern United States, a single seasonal application of 200 mg. per square foot is about as effective as two seasonal 100 mg. applications while the cost of the single application is lower. To obtain the 200 mg. dosage, a 5 per cent concentration of insecticide is used; and for a 100 mg. dosage, a 2.5 per

concentration. A 5 per cent solution of DDT contains 5 gm. DDT per 100 ml. solution; one ml., therefore, contains 50 mg., and the 200 mg. dosage requires the spraying of 4 ml. of solution per square foot of surface. Stierli and others (1945) recommend a nozzle which delivers a fan-shaped spray with an angle of 80° and operating at a pressure of 30 to 70 psi. A gallon of the spray, distributed evenly over 100 square feet, represents 4 ml. per square foot; thus the 5 per cent concentration leaves a deposit of 200 mg. per square foot, and the 2.5 per cent spray 100 mg. The nozzle should be held 15 to 18 inches from the wall to produce a swath width of 18 to 30 inches. With a discharge rate of 0.24 gallons per minute, 4 ml. of spray can be applied per square foot if approximately 230 square feet of surface are treated in one minute.

The residual insecticides may be applied as solutions, emulsions, or wettable powder suspensions. The type of building, the surface to be sprayed, availability and cost of materials, transportation problems, etc., will determine the selection of the spray formula. Five per cent DDT in kerosene has been widely used, but as the solubility of DDT in kerosene is low, large amounts of the spray must be transported. An emulsion concentrate simplifies transportation problems. A "standard" emulsion formula for DDT has been given above, but it may be useful to refer to formulae recommended by Stierli, Simmons, and Tarzwell:

SUMMER DDT CONCENTRATE

DDT . . . . .	3 pounds
Xylene . . . . .	3 quarts
Triton X-100 . . . . .	6 fluid ounces

Dilute 1 part of concentrate to 6 parts of water to make a 5 per cent spray.

WINTER DDT CONCENTRATE

DDT . . . . .	2 pounds
Xylene . . . . .	1 gallon
Triton X-100 . . . . .	0.2 quarts

Add one part of concentrate to 3 parts water for 5 per cent spray.

The necessity for the summer and winter formulae is due to the lowered solubility of DDT in xylene in cold weather, and these concentrates were designed to take advantage of the greatest dissolving ability of xylene and the smallest amount of surfactant necessary to produce a satisfactory emulsion. The winter formula is satisfactory for use at temperatures as low as 32° F.

Wettable powders, which can be made into sprays of the desired strength by following directions supplied by the manufacturer, are often especially effective as contact sprays, but as a visible deposit is left on the walls they are more suitable for barns and outbuildings than for houses. However, in rural tropical areas the deposit may not be objectionable in houses, and it may be desirable to take advantage of the greater effectiveness of this type of spray.

Reference should be made to *Entoma*, the yearly directory of insecticides and manufacturers of insecticides published by the Eastern Branch of the American Association of Economic Entomologists, Department of Entomology, University of

Maryland, College Park, Maryland. Sources of supply of insecticides and dispersing equipment may be determined by reference to this directory.

**Insecticide-Resistant Strains of Insects.** An interesting and somewhat alarming phenomenon which has occurred following the widespread use of DDT as a residual insecticide is the building up of housefly populations which are resistant to DDT. In various parts of the world it was observed that DDT was becoming less and less effective in controlling flies. Substitution of another insecticide brought about temporary relief, but liberal use of chlordane and benzene hexachloride was followed by the appearance of strains resistant to these compounds also. In the laboratory resistant strains have been developed to all the residual type insecticides, and the degree of this resistance can be appreciated from the statement by March and Metcalf (1950) that their "super-Bellflower" strain is more than 3,000 times as resistant to DDT as the ordinary laboratory strain, while their "super-Pollard" strain is approximately 10,000 times as resistant to lindane and more than 3,000 times as resistant to dieldrin as the laboratory strain. Furthermore, the DDT resistant strains are also more resistant to related compounds. In building up a resistance to an insecticide, presumably the more resistant individuals survive the ordinary lethal contact; with continuous exposure, a rapid selection of the hardier members continues, and within a relatively short time multiplication of the resistant strain results in a high density of flies that cannot be controlled with the previously effective insecticides. If only a small segment of the fly population is thus affected the resistance may be lost through breeding with nonresistant forms, but with widespread use of the residual insecticides the resistance may spread generally throughout the entire population of large areas. March and Metcalf report that their Bellflower strain lost none of its DDT resistance through 35 generations of nonexposure to DDT, while Bruce and Decker (1950) reared 30 generations of a DDT resistant strain in the absence of DDT without a loss of the resistance in the final progeny.

The mechanism of the resistance appears to be a metabolism of the DDT. Sternburg and others (1950) found that in the resistant flies DDT is rapidly converted to DDE [2,2-bis (*p*-chlorophenyl)-1,1-dichloroethylene]. According to Perry and Hoskins (1950) this detoxification of DDT by resistant flies is largely prevented by treatment with piperonyl cyclonene; thus, there seems to be an interference of the enzymatic process which converts DDT to DDE. DMC [1,1-bis (*p*-chlorophenyl) ethanol] has been shown to have a synergistic effect when used in collaboration with DDT, chlordane and dieldrin against resistant flies.

Other arthropods that have developed resistance to DDT and other halogenated hydrocarbons are bed bugs, fleas, body lice, cockroaches, ticks and mosquitoes. Among the latter are *Aedes sollicitans*, *A. taeniorhynchus*, *Culex fatigans* and *C. tarsalis*. In most parts of the world anti-malarial programs have not been affected by development of DDT-resistant anophelines; however, in Greece *A. maculipennis* and in one area of Indonesia *A. sundanicus*, have shown evidence of resistance. It is not impossible that other vector species may become resistant. Other anophelines have been undergoing changes in behavior patterns as a result of contact with residual sprays in houses. These tendencies may eventually jeopardize the modern approach to malaria control.

**Control Versus Eradication.** The control of arthropods signifies their reduction in numbers to the point where they are no longer annoying or dangerous. Depending upon the numbers of infected and susceptible people, when the diminution of a

or population reaches a certain point, disease transmission stops; thus elimination of the disease does not require the eradication of the vector. However, in order to keep the vector density down to safe levels, continual application of control measures is necessary, and in the complete absence of the disease and a low vector population, this often seems futile. It may be difficult to justify the expenditure of large sums of money for malaria control in places where there is no malaria and apparently no anophelines. The danger in such a situation lies in the fact that with relaxed vigilance the vector population may again increase rapidly to the point where the parasites, made available through relapses or introduction of new cases, can be picked up by the mosquitoes. A happier solution would be the complete extermination of the vector from the country during the enthusiasm of the original campaign.

There have been many demonstrations that disease vectors can be eradicated if enough money and energy is devoted to the project. Through dipping and quarantine, the Texas fever tick has been eradicated from the southern United States. The success of the eradication of *Anopheles gambiae* from Brazil (Soper and Wilson, 1943) has encouraged the belief in the possibility of eradication of other mosquito species as well. Under the supervision of the Pan-American Sanitary Bureau, a concerted attack is being made upon *Aedes aegypti* through most of Latin America, and according to the monthly reports published in the Boletín de la Oficina Sanitaria Panamericana this mosquito appears to be disappearing from this part of the world. *Anopheles gambiae* has also been exterminated in Egypt following its introduction in 1942. It must be noted that both *A. aegypti* and *A. gambiae* are dangerous because of their highly domestic habits, and this also makes them more susceptible to attack, particularly through the use of household sprays. Also, the eradication campaigns against these species were limited to areas into which the mosquitoes have been introduced. The extermination of indigenous mosquitoes, especially those with less domestic habits, is a more complicated problem, for the last specimens remaining in obscure and marginal ecological niches would have to be found and killed. That certain indigenous species at least can be eliminated from circumscribed areas is demonstrated by the results obtained against *Anopheles pseudopunctipennis* in Chile and against *A. darlingi* in coastal British Guiana and in Venezuela. These species, however, are also peculiarly susceptible to attack, the former because of the circumscribed valleys of the Chilean Andes in which all adults and larvae could be reached by the methods employed, and the latter because of its strong domestic habits. One should note that Giglioli (1948), who directed the *darlingi* campaign in British Guiana, carefully points out that in an area such as coastal British Guiana, where there are no natural barriers to the reintroduction of *A. darlingi*, the use of residual DDT will eradicate this species, but that it is a palliative measure that may have to be continued indefinitely. However, as *A. darlingi* is always closely associated with man, and so probably could immigrate only along routes opened by camps, settlements, etc., it may be possible to prevent reintroduction by setting up barriers of residual DDT at certain strategic points along the periphery of the cleared area, and it may not be necessary to continue residual applications within the cleared area itself.

Attempts also have been made to eradicate *Anopheles superpictus* and *A. marovii* from Cyprus, and *A. labranchiae* from Sardinia. Early results were

promising, but it appears that *A. labranchiae* can survive in very small numbers in spite of intensive control procedures. Furthermore, Logan (1950) estimates the cost of the Sardinian demonstration to reach about 12 million dollars by the end of 1950. Eradication, although of great advantage in combating certain especially susceptible species, is not feasible for others. As Soper (1941) said, "One would not recommend eradication of *Anopheles quadrimaculatus* in the United States. . . ."

#### RESUME OF THE ARTHROPODS OF MEDICAL IMPORTANCE

**Order Diptera.** The order *Diptera* is composed of a large number of families of flies, which may be grouped into two suborders: the *Orthorrhapha*, which includes the midges, black flies, mosquitoes, and horseflies, and the *Cyclorrhapha*, which includes the houseflies, stable flies, and tsetse flies. The bloodsucking habit has arisen independently in each of these suborders. The mouth parts of the bloodsucking *Orthorrhaphous* flies consist of two mandibles and two maxillae, which are needle-like and puncture the skin, and two other stylets, the labrum and hypopharynx, which fit together to form a tube through which the blood is sucked into the digestive tract. The hypopharynx possesses a small duct through which saliva containing an anticoagulant is injected into the wound. These six stylets when not in use are kept within the proboscis sheath or labium. The labium ends in two small lobes called labella. In the *Cyclorrhaphous* flies the tissue-piercing mandibles and maxillae have been lost. Most of these flies are not bloodsuckers but feed upon liquid foods which are sucked up through minute openings in two large fleshy pads at the end of the proboscis. These pads are the labella, which have become enlarged to take over the function of food ingestion. A reduction in the size of the labella, accompanied by a strengthening of some prestomal teeth at the end of the proboscis, has made it possible for some of the *Cyclorrhapha* to become bloodsuckers.

**FAMILY HELEIDAE (CERATOPOGONIDAE).** *The biting midges (also called sand flies).* The bloodsucking forms are found in the genera *Lasiohelea*, *Leptoconops*, and especially *Culicoides*. They are very small, but when they attack in numbers they are extremely annoying. They are vectors for the filarial worms, *Dipetalonema perstans* and *Mansonella ozzardi*. The breeding places of the *Heleidae* include fresh and salt-water swamps and marshes, lakes, pools, streams and tree holes. The larvae do not swim free in the water, but burrow down into the mud and debris, or embed themselves in mats of algae. The larvae develop very slowly, requiring from several weeks to as much as several months to become mature, during which time they pass through four stages or instars. In temperate regions the winter is passed in the larval stage. The pupa, which lies quietly at the surface of the breeding place, gives rise to the adult after about five days.

Personal protection against the bites of these flies may be obtained through the use of the newer repellents. Application of 5 per cent DDT in kerosene screens has protected persons within dwellings for about three months. Destruction of the immature stages in the breeding places is difficult because the submerged larvae are not readily reached by ordinary larvicides. However, successes have been reported through the use of 1 pound per acre of DDT in oil solutions, 12 to 1

nds per acre of a 10 per cent DDT dust, and 3 to 5 gallons per acre of DDT solution. Drainage and reclamation of marshes will destroy breeding places.

**FAMILY PSYCHODIDAE.** *The moth flies and sandflies.* The bloodsucking members of this family will probably be referred to in the medical literature as *phlebotomus* for a long time to come, although taxonomists are splitting this large genus into smaller generic units. *Phlebotomus* species are tropical and subtropical in distribution. The adults are readily recognized by the slender, hairy bodies, the long legs, and narrow hairy wings which are held erect over the thorax when at rest. The larvae breed in soil heavily charged with organic matter; there are four larval stages and larval development requires from two weeks to about three months. The pupal stage lasts a week or two.

These insects are responsible for the transmission of phlebotomus fever, Oroya fever, and leishmaniasis. Control of the immature stages is difficult because of the inaccessibility of the terrestrial breeding places. The adults, however, are particularly susceptible to residual insecticides such as DDT. They move in short, darting flights, coming to rest at frequent intervals upon a convenient surface. When approaching a house to procure a blood meal from the inhabitants, the females will come to rest on the outside and inside walls, and are readily killed by short contact with a residual spray. Not only is residual house spraying of DDT extremely effective, but also the application of DDT to stone walls and other proposed selected resting surfaces and shelters may bring about a considerable degree of area control (Hertig and Fairchild, 1948). Dimethyl phthalate is an effective repellent, and has been shown to prevent troops from acquiring phlebotomus fever.

**FAMILY CULICIDAE.** *The mosquitoes.* The true bloodsucking mosquitoes are considered by taxonomists to belong to the subfamily *Culicinae*, and are distinguished from all other flies by the combination of three characters: the type of wing venation, the presence of scales on the wing veins and the long proboscis containing the piercing-sucking stylets. A total of about 2,000 species occur throughout the world, and taxonomists distribute the species among 27 genera, of which the most important are the cosmopolitan *Anopheles*, *Aedes*, *Culex* and *Wyeomyia*; the nearctic and neotropical *Psorophora*; the neotropical *Haemagogus*; the Oriental and Australasian *Armigeres*; and the Ethiopian *Eretmapodites*.

The life cycle of the mosquitoes includes the egg, four larval stages, the pupa, and the adult or imago. Each larval stage is followed by a molt, and when the fourth stage larva sheds its skin the pupa emerges. The time required for development of the immature stages varies according to temperature, food supply, and upon inherent physiological differences between species and genera, but, in general, species of *Anopheles* and *Culex* require two or three days for the incubation of the eggs, 10 to 14 days for larval development, and two or three days for the pupal period. Following emergence, the adult females pass through a preoviposition period of about three days to a week. The entire life cycle, therefore, is usually completed in two or three weeks.

In temperate and tropical regions, breeding may be more or less continuous during the favorable seasons, depending upon the availability of suitable water; there may be several broods a year. In areas where the breeding season is interrupted by winter, the mosquitoes undergo a period of hibernation. In *Anopheles* and *Culex* it is the fertilized adult which hibernates; it passes the winter in a suit-

able shelter. Species of *Aedes* and *Psorophora* hibernate in the egg stage. *Anopheles walkeri* is capable of passing through the winter in the egg stage, and a few species of *Anopheles* and certain plant-cavity breeding mosquitoes hibernate in the larval stage.

The immature stages of all mosquitoes are aquatic; water is essential for the survival and growth of the larvae and pupae, and also for the hatching of the eggs. Eggs of the temporary rain-and-flood-pool-breeding *Psorophora* and *Aedes* are deposited on the damp soil of marshes, the margins of pools, or even in the depressions in the ground where they may remain dormant for weeks or months. Other species of *Aedes* are adapted for breeding in plant cavities or artificial containers. *Aedes aegypti* is the best known of this group, and its eggs are deposited just above the water line where they may dry and remain viable for months. Eggs of *Culex* are thin shelled, and are placed directly upon the surface of the water by the ovipositing female. They must hatch within two or three days, and there is little evidence that they can withstand desiccation. *Anopheles* eggs also are laid directly upon the surface of the water, and ordinarily they also hatch within two or three days. However, they are relatively thick shelled, and there is evidence that they may be quite resistant to dewatering provided they have undergone a suitable period of embryonation and are lying in moist soil. After completing its development within the shell, the larva may wait for free water in order to hatch for as long as three weeks. The ability to delay hatching could explain the sudden appearance of large numbers of larvae along margins of reservoirs with fluctuating water levels; furthermore, it might be of importance to the existence of the species during unfavorable seasons and in submarginal zones of distribution where survival may be accomplished in part through dormant eggs whose presence is unsuspected.

Larvae are unable to withstand prolonged desiccation but pupae are more resistant. Darrow (1949) found a correlation between evaporation rate and mortality of *Anopheles quadrimaculatus* larvae and pupae stranded along the shores of the natural breeding places; even under the most favorable conditions, mortality of the fourth stage larvae was complete after 48 hours. Adults were able to emerge successfully from pupae stranded on moist soil.

Although living in an aquatic environment, the larvae and pupae are air breathers. All larvae except those of the anophelines possess a breathing tube or siphon on the next to the last abdominal segment; at the tip of the siphon there are two spiracular openings, which lead to a pair of tracheal tubes running forward into the body. The anopheline larvae lack the siphon, but the two spiracles are surrounded by four small plates which help the spiracles to maintain contact with the air. In the genus *Mansonia* and a few species of *Ficobia* the siphon is pointed; the larva jabs the siphon into the tissues of plants and thus is able to obtain oxygen without the necessity of coming to the surface of the water.

The larvae are equipped with mandibles and maxillae, with which they ingest small particles of food which are swept into the mouth by means of the mouth brushes. Feeding takes place at the surface film, especially on the part of the anophelines, or along the sides and bottom of the breeding place. Larvae of *Megarhinus* and of a few other species are predaceous; their strong, specialized mouth parts permit them to feed upon the larvae of other species of mosquitoes.

larvae appear to be omnivorous, sweeping into the mouth all particles small enough to be ingested. Dead organic material may be ingested, but perhaps the important source of food is living algae and protozoa. Some authors believe bacteria may be utilized as food, especially by the young larvae, and it has been claimed that even materials in solution or in colloidal form may be of nutritional value. It is evident that the living micro-organisms also furnish essential growth-promoting substances, among which are thiamin and riboflavin; folic acid appears to be necessary for pupation; and additional factors, presumably supplied in nature by the micro-organisms, are necessary.

Almost any type of water is used by the mosquitoes as a breeding place, provided it is quiet, provides reasonable protection from enemies, and contains an adequate food supply. One of the most interesting, as well as an extremely important phenomenon with respect to control of mosquitoes, is the fact that a species or group of species may exhibit a marked preference for, if not an actual dependence upon, a certain type of breeding place. Various factors combine to make available waters either suitable or unsuitable as breeding habitats. Open, shallow waters favor many species, including the majority of the most dangerous malaria-carrying *Anopheles*, but are unsuitable for other species which are found only in densely shaded locations. Inorganic and organic materials determine suitability of the water for many species. It is obvious, therefore, that the larvae have had to undergo a number of physiological adaptations to permit survival in various types of habitat. However, it seems that the proper breeding site is selected by the ovipositing female. Just what mechanisms are involved are not yet clear, although one factor seems to be the visual responses of the females to differences in light intensities at the water surface.

The principal types of breeding places are as follows:

1. *Lakes, swamps and marshes, impoundments*, and the like are especially important as sources of *Anopheles*, as these mosquitoes require quiet bodies of relatively clean water for breeding. In a large body of water such as a lake or impoundment the larvae will not be found in open, windswept areas subjected to wave action; the larvae must be protected from severe water movements as well as from their enemies by vegetation and flottage. One finds the larvae concentrated in certain favored areas which can be spotted readily by an experienced collector. Attempts have been made to correlate the presence of larvae with certain physico-chemical factors, such as pH, dissolved oxygen, nitrogen, food organisms, and so on, but it seems that one of the most important factors in determining the suitability of a breeding site within a large body of water is the physical character of the vegetation as it breaks through the water surface. The margin of the leaf or stem at the water surface has been termed the "intersection line"; this intersection line can be measured per unit of water surface, and it has been shown (Reboom and Hess, 1944) that there is a correlation between the extent of this intersection line and the numbers of *Anopheles* larvae. Plants differ in their ability to create an intersection line; a sparse covering of large lotus leaves produces a low intersection line, and if the water level drops so that only the narrow margins are projecting above the water, the intersection line drops to a small value. Breeding is almost nonexistent. Grasses and mat-forming types of vegetation produce high intersection line values, and breeding in them is most intense.

2. *Streams.* Running water ordinarily is not suitable for mosquito breeding; however, in the Oriental and Indian regions there is a group of *Anopheles*, including the dangerous malaria-carrying *A. minimus* and *A. fluviatilis*, which are especially adapted to breed along the margins of streams, in areas protected by vegetation and other obstructions.

3. *Temporary and semipermanent flood or rain pools.* These are the breeding sites of the *Aedes* and *Psorophora* species whose eggs are deposited by the female in dry depressions on the ground or along the margins of fluctuating waters. The mosquitoes are adapted to go through the larval development rather rapidly in temporary breeding places. If continued rains keep rain pools filled with water, they lose their temporary character and become more or less permanent breeding places of *Anopheles* and other genera. The reason for the increase of malaria in the tropics during the rainy season is the invasion of the innumerable rain pools by the quiet water breeding species of *Anopheles*.

4. *Plant cavities.* The *Sabethine* group of mosquitoes, and a few species of other genera, utilize only various types of water holding plant cavities as breeding sites. Usually, each species is found in only a certain type of habitat, and again the reasons for the selection of a given kind of breeding place for oviposition on the part of the female are of great interest but are unknown at the present time. This type of breeding place includes bamboo internodes, stubs of cut bamboo, bromeliads, tree holes, pitcher plants, fallen coconut husks, palm bracts, and many other objects in which water collects. A few tropical species will even be found in films of water that collect on small fallen leaves in the rain forest.

5. *Fissures and crevices* in rocks along streams furnish breeding sites for certain species which are not found elsewhere.

6. *Artificial water receptacles.* A few species, notably *Aedes aegypti* and *Culex pipiens*, utilize rain barrels, tin cans, vases, and the like.

The points in the life cycle and behavior of the adult mosquitoes that are especially important in their relation to the epidemiology of diseases are reproductive capacity, longevity, host preferences, resting places, and flight habits. Species undergoing a rapid life cycle and which produce abundant eggs are potentially capable of building up populations dense enough to be involved in disease transmission, provided extensive breeding areas are available and also that the females attack the human host in large numbers and live long enough to incubate the infective stage of the disease organism. Only the females are bloodsuckers; the males feed upon plant juices such as nectar of flowers and decaying fruits. There is some preference for certain types of host animals; some species, particularly the genus *Culex*, feed upon birds; *Aedes* and *Anopheles* appear to attack especially domestic animals and man. In a malarious area, the dangerous *Anopheles* species are usually marked by a preference for man that drives them into houses to feed. The habit of entering and remaining in houses for a time is termed "domesticity"; it must be distinguished from "anthropophagy," which refers only to the attractiveness of man to the mosquito. Usually, the malaria-carrying species (*A. gambiae*, *A. darlingi*, *A. sacharovi*, etc.) show a high degree of domesticity as well as strong anthropophagous habit; however, there are a few dangerous malaria vectors, such as *A. bellator* in Trinidad and *A. minimus flavirostris* in the Philippines, which do not rest in houses and may not even feed upon man to any extent in areas

most important to bear this in mind in connection with the use of residual  
s in malaria control.

Mating is thought to take place usually through the mechanism of swarming;  
ever, there is evidence that swarming of the males is not always a precopulatory  
ity. Males congregate in small or large swarms at dusk, usually above an  
t such as a bush; females are believed to fly through the swarm and emerge

From U. S. Dept. of Agriculture.

Fig. 7-2. *Anopheles quadrimaculatus*—male and female.

d with a male. Some species such as the domestic *Aedes aegypti* do not require  
arm. Roth (1948) has demonstrated that males respond to sounds made by  
ying females by attempting copulation; these sounds are detected by means  
e bushy antenna. Males may even be stimulated by sounds made by tuning  
of proper frequencies. Changes in illumination appear to be another factor  
nditioning the males. They become active at twilight; this may be noted in  
n captive colonies as well as in wild populations, and it is sometimes possible  
duce swarming of males and hence promote copulation of *Anopheles* which  
rdinarily difficult to rear in the laboratory by subjecting caged colonies to  
e light of certain intensities.

ertilized females, having partaken of their first blood meal, need from three  
to a week or more to mature their first batch of eggs. Following oviposition,  
female feeds again, and after about two days lays her second batch of eggs,  
which she again feeds. This process is repeated throughout the adult life of  
nsect. There are usually 30 to about 200 eggs in each batch, and a female  
produce a total of a thousand or more eggs. Enough spermatozoa are stored  
e spermathecae following a single copulation to fertilize about all of the  
however, pairing probably occurs several or many times during the lifetime  
e adult.

Most of the adult life of the mosquito is spent in various types of natural  
g places, which include hollow trees, overhanging stream banks, bushes,  
es, and other types of vegetation. The undersides of bridges, culverts, dark

sheds and barns furnish resting places for a few species, particularly among the anophelines.

The female mosquito is faced with the necessity of flying between the breeding waters, the source of blood, and the diurnal resting places, and the distance females can fly from the breeding place determines the extent of the area

included in malaria control operations.

Ordinarily, most anophelines do not fly more than a half mile to a mile, and it has been the practice to control the breeding places of anopheline malaria vectors in a belt of a mile in width surrounding inhabited areas. Anophelines have been observed to fly from 3 to 10 miles under favorable conditions. Such flights might be considered to be in the nature of migrations, rather than representing usual movements, and are probably usually accomplished through a series of short flights. Some culicine mosquitoes, particularly pest species *Aedes*, have been reported to fly from 4 to 40 miles, and to cause severe annoyance within this zone of migration.

The longevity of the adult varies according to species and climatic factors; overwintering females live several months, but during the active season it is probable that females of most species do not survive much more than a month. In laboratory colonies *Anopheles* adults have been observed to live for a month or two. The importance of the adult longevity in disease transmission is illustrated by observations such as those which

From U. S. Dept. of Agriculture.

Fig. 7-3. Resting position of *Culex* (above) and *Anopheles* (below).

indicate that during dry weather malaria transmission is interrupted in parts of India because of the early death of the vector, *A. culicifacies*. According to Hack (1940) quartan malaria is absent from the Nile delta because *A. pharoscensis* is unable to live long enough in this hot, dry climate to permit the slowly developing quartan malaria sporozoites to mature. *A. superpictus* and *A. sergenti* are adapted to desert conditions, and where these longer-lived species occur, quartan as well as other malarias are found.

Some mosquitoes are especially adapted to hot, dry weather. *Aedes* *egypti* is extremely hardy, and may live for months, although it also survives best in a moist atmosphere. For the arboreal *Haemagogus* species a moist environment is actually detrimental; these mosquitoes can be reared best in the laboratory in a dry, warm incubator (Bates, 1947). The metallic coloration of these mosquitoes

be an adaptation to their hot, dry, arboreal environment, and it is interesting to note that species of other genera which have habits similar to those of *Haemagogus* may also have a metallic coloration and are equally long-lived in the adult stage. These mosquitoes breed in small collections of water caught in plant cavities during the rainy season, and the dry season survival of such species may depend on the ability of the adults to live for long periods.

A more detailed account of general mosquito biology may be found in a recent book by Bates (1949).

Mosquitoes represent the most important single group of arthropods of medical interest, as they are responsible for the transmission of malaria, filariasis, yellow fever, dengue, the encephalitides, and Rift Valley fever. They are serious pests, cause great economic loss through nondevelopment of badly infested areas and annoyance and death to livestock.

**Mosquito Control.** The control of mosquitoes has undergone great improvement since the advent of the more toxic and residual insecticides. Mosquito control may be said to have three objectives. First, there is pest control, in which all the species in an area which annoy man are attacked through blanket measures. Second, there is species control, the purpose of which is to attack only the vector species. This concept came into being especially through the demonstrations that only certain species of *Anopheles* were important as malaria vectors, but more recently the use of residual insecticides in houses has caused a de-emphasis of this approach. The third objective, eradication, was discussed above.

Defensive measures against mosquito attack involve the wearing of protective clothing, the use of the newer repellents, and mosquito proofing of houses. In the United States 16-mesh galvanized screen wire is satisfactory for screening, but in tropical areas, particularly near the seacoast, copper screening is more lasting. Larger mosquitoes such as *Aedes aegypti* and *Anopheles bellator* are able to pass through 16-mesh screen and where protection is desired from such small species, finer mesh screen may be necessary. Mosquito proofing of rural houses requires not only the screening of windows and doors, but also the elimination of all cracks and crevices in walls, floors and ceilings by papering with a heavy kraft paper or asphalt roofing paper, the covering of larger holes with boards or strips of tin, and the use of a removable screen before fireplace openings.

**DESTRUCTION OF MOSQUITO LARVAE.** Of the many natural checks on mosquito larvae, one of the most effective is the predatory action of fish, and the best known of these predators is *Gambusia*. These fish are highly efficient in seeking and feeding upon the larvae; they reproduce rapidly and have adapted themselves to various types of breeding places into which they have been introduced in many parts of the world.

Naturalistic larval control measures include the planting of dense shade plants along the banks of streams, the periodic flushing of such streams through the use of a series of dams equipped with flood gates or automatic valves, intermittent irrigation of rice fields, and the increase in salinity of brackish waters through the use of dikes and tide gates. The presence of domestic animals in houses will divert weakly anthropophagous anophelines such as *Anopheles tritaeniorhynchus* and *A. messeae* from the human hosts. In the United States, perhaps the most effective single naturalistic control measure has been the water man-

agement program of the Tennessee Valley Authority in its system of huge reservoirs. Malaria control is part of the overall plan of the reservoir. Prior to impounding, the shoreline of the proposed reservoir is cleared of vegetation, and following completion of the dam, the reservoir should be filled during the winter months, which would permit stranding and removal of flotsam before breeding begins. The ideal program for water level management includes a flood surcharge with the water up to the top of the gates during the nonbreeding winter season for the purpose of stranding all flotsam and drift; a drop in water level to the normal operating level in the early spring, at which time very little breeding takes place, a period of cyclical fluctuation of the water level during the moderate breeding of the early summer, in which the water is raised and lowered approximately a foot at weekly or 10-day intervals; and a weekly cyclical fluctuation combined with seasonal recession during the heavy breeding season of late summer. The purpose of the seasonal recession is to keep the maximum pool level constantly retreating from the encroaching mat of marginal vegetation, while at the same time the cyclical fluctuation continues to operate in its destruction of those larvae that have managed to become established.

The actual mechanism involved in the killing of the immature stages by fluctuating water levels are twofold. From Darrow's (1949) observations it seems evident that most of the larvae and pupae are drawn by the receding waters out of the protection of their breeding sites into open water, where fish and other predator wave action, and possibly lack of food organisms, combine to eliminate them. In vegetated areas and with slow draw down, many larvae and pupae are stranded on the shore, where most of them fail to survive an eight-hour exposure. Death is due to either the direct effects of desiccation or to the activity of insect predators.

**DRAINAGE.** According to Herms and Gray (1940), drainage is "in most cases the most effective antimosquito measure since it robs the mosquito of its breeding place and thus affords the best possibility of complete and relative permanent abatement." Drainage may be effected through surface ditches, which connect low-lying areas with a main drain. Such ditches may be constructed with hand labor or with special ditching machinery such as dragline excavators, and sometimes by blasting simultaneously a series of dynamite charges. Surface ditches must be maintained, or they themselves become mosquito producers. They must be kept free of vegetation and other obstructions; scouring by heavy run off may cause water-holding depressions to form along the bottom of the ditch; or banks may cave in. It may be more economical to line the ditch with concrete or masonry inverts. Subsoil drain tiles may be used effectively in many places; they have the advantage of not in themselves creating breeding sites. Occasionally, it is possible to employ vertical drainage for a body of water trapped over a bed of hard pan. Control of breeding in extensive coastal marshes may involve reclamation employing dikes, drainage ditches, tidal gates, and pumps. Sometimes areas that cannot be drained may be filled, or a swampy area may be deepened, cleared, and transformed into a nonbreeding recreational pond.

All of these engineering measures require technical knowledge outside the scope of this book. A trained engineer is an essential member of a competent malaria and mosquito control team, wherever problems are of such a scope that environmental sanitation is necessary. All members of the team must have a thorough knowledge

the biology of mosquitoes; without it, control may be purposeless or even detrimental. For example, as noted above, clearing and impoundment of some swampy marshy areas may convert a breeding area into an open water pond in which larvae cannot survive; on the other hand, thoughtless clearing of a shaded pond may make the water unsuitable for harmless, shade-loving species of mosquitoes, but permit the breeding in tremendous numbers of sun-loving, dangerous malaria vectors.

**LARVICIDES.** Larvicides must be resorted to for control of breeding in areas amenable to naturalistic measures or where the latter are not economically feasible. Larvicidal oils and Paris green have largely been supplanted by the newer, more toxic insecticides and, of these, DDT has been the most widely used. A dosage of 0.1 to 0.2 pounds DDT per acre as a dust, or 0.05 pound DDT in solution may be used without great danger to fish or other aquatic organisms in a lake or pond, particularly if applied only to the marginal and vegetated areas in which breeding occurs. Frequently, 0.1 pound of DDT per acre in oil solution is used, but this heavier dosage should be used only after due forethought to the possible effects upon fish and wildlife. Where the latter do not constitute a problem, 0.1 pound per acre may be considered as the standard dosage.

For use as a larvicide, a 1 to 5 per cent solution may be made in kerosene or fuel oil. In order to distribute the DDT at the rate of 0.1 pound per acre, only one quart of the 5 per cent solution is required. Although this may be done with difficulty from an airplane, for hand distribution it is simpler to spray a gallon of the 5 per cent solution. Where special precautions are necessary to avoid killing of fish, the gallon of spray should contain 0.05 pound DDT. Ferguson and others (1947) selected No. 2 fuel oil as the solvent, and state that the larvicidal effectiveness was increased by the addition of a spreading agent, such as 0.5 per cent kerosene. In 1956. The larvicide may be distributed effectively by means of a knapsack sprayer equipped with a nozzle that delivers a fine mist spray. The operator treats the breeding waters by walking along the shores or through the breeding place at an angle to the wind and allowing the mist to drift with the wind across the water. The pressure in the sprayer should be from 30 to 50 pounds, and the operator should proceed at the rate of about 75 feet per minute. Moderate winds will distribute the mist across the water for about 30 feet, and so the operator should treat the entire breeding place in 30-foot swaths. This may be done on foot, or, if the water is too deep, by boat. The advantages of *Anopheles* control by this method over the older use of oil larviciding, which often required several gallons of oil, heavy equipment, and storage and transportation of large quantities of oil, are obvious.

More elaborate equipment may be necessary for control of extensive breeding areas, and various types of spray rigs are available on the market, from power sprayers to fog machines. Airplane application of insecticides, either as sprays or thermal aerosols, has simplified control of extensive breeding areas not accessible by other means. Various types of sprayers have been adapted for both civilian and military combat planes, including the Husman-Loncoy unit, the breaker-bar sprayer, and exhaust generators. The 5 per cent solution in fuel oil may be sprayed from aircraft, but it is said that the addition of 10 to 20 per cent by volume of motor oil (S.A.E. 10 to 80) improves the efficiency of the larvicide. With an exhaust

generator, a 20 per cent solution of DDT is used, and liberated through an extension of the exhaust stack, where it is broken up into fine spray and aerosol particles. The types of exhaust generators and effectiveness of the aerosols and sprays produced are discussed by Krusé and his associates (1946; 1949).

For culicine larvae, heavier dosages of DDT, up to 0.4 pound per acre, may be necessary. In some areas, especially where larvae have become resistant to DDT, it is advantageous to use other larvicides. Good results have been obtained with the application of 0.1 pound per acre of lindane, the gamma isomer of BCH, dieldrin and heptachlor. In small ponds, burrow pits, etc., where fish and other wildlife do not present a problem, application of three pounds of DDT or one pound technical BCH will control larvae for several weeks. One pound of dieldrin per acre will prevent breeding for one to two years. Larvicides are usually applied as oil solution, but for heavy dosages emulsions are used. Better penetration through vegetation is possible with the use of granulated insecticide such as coarse tobacco stem dusts or clay pellets which have been impregnated with DDT, BCH or dieldrin.

For control of *Aedes aegypti*, vases and other small water containers may be treated with a saturated solution of DDT in 95 per cent ethyl alcohol dispensed with an eye dropper at the rate of one drop to a quart of water. Fire barrels treated with a 35 per cent xylene emulsion concentrate at the rate of about 1 ml. to 50-gallon barrel were kept free from larvae for four months or more.

**DESTRUCTION OF ADULT MOSQUITOES.** The development of the stable, residual type insecticides has made possible a new principle in the control of mosquitoes. Formerly, greatest promise of success lay in an attack on the larvae, as they are confined to an aquatic environment. The adults, on the other hand, leading an aerial existence, and resting in out of the way places, cannot be reached by the ordinary insecticides, and even though trapping, hand catching, and spraying of dwellings might kill off large numbers, enough females escape to permit breeding to continue undiminished. Systematic house spraying with pyrethrum to kill adult mosquitoes has been very effective in stopping transmission of malaria, but it usually had little effect upon the density of the mosquito population.

The effectiveness of the *residual insecticides* lies in the fact that a poisonous coating may be placed on the walls and ceilings of dwellings and other shelter which will continue to kill almost every adult which comes to rest in these places for weeks or even months. It is important to understand the habits of the adult of the species against which the residual spray is to be used. Most anopheline which are disease vectors enter houses to feed upon man and, after the blood meal, they usually rest for a time upon the wall or ceiling of the dwelling. Such species are susceptible to a residual spray, and this is especially true of the most highly domestic and hence most dangerous species, such as *A. darlingi*. Residual spraying of houses not only immediately stops practically all disease transmission by the highly anthropophilic and domestic species, but because the females enter houses by preference, the residual spray reduces and may even stop larval breeding. The Giglioli has been able to eradicate *A. darlingi* from coastal British Guiana through the use of *residual DDT in houses*. Most anophelines are not so strongly attracted to man, but feed indifferently upon man or his domestic animals. Nevertheless,

ual spray in houses is highly effective in preventing disease transmission by individuals which enter houses to feed upon man. Trapido (1946) describes action of residual DDT against *Anopheles albimanus* as manifesting itself in ways: (1) in the marked reduction of adults in houses for approximately months; (2) in the activation and consequently the prevention of feeding by individuals that entered the houses by passing through the interstices between pane walls; and (3) by the high mortality after 24 hours of those individuals did manage to obtain a blood meal. After four months, in the thatched roofed, sided dwellings of these tropical, Panamanian villages, the residual deposit prevented most engorgement from taking place, but the mosquitoes began to ve the 24-hour period of observation. In these conditions, treatment at four h intervals is indicated. Repeated four-month treatments were progressively ive, and Trapido states that in the third four-month post-treatment period the ction of blood-engorged *Anopheles* surviving 24 hours reached the impressive e of 99.9 per cent. If sheds, barns, and other resting places are treated, there be a marked reduction in density of even moderately domestic species. There few dangerous, highly anthropophilic species which cannot be controlled by ual DDT in houses. Thus, in Trinidad, it has been shown (Rozeboom and l, 1942) that the malaria-carrying *Anopheles bellator* feeds mostly out of s, and thus it would not come into contact with the walls of houses. It is of est to note that in southern Brazil this species does enter houses in large num- Although it was feared that *A. minimus flavirostris*, which does not rest in es, might not come into contact with a residual deposit (Smith and Dy, 1949), has been highly successful in the control of this species in the Philippines. Adult mosquitoes may be killed as they rest in woods, or other natural shelters, hgh the use of aerosols or sprays, applied either with hand sprayers, power vers, thermal aerosol machines, or by plane. Such measures are often useful otecting military or other personnel who must remain in the infested areas.

**Family Simuliidae. The black flies.** The adult black fly is characterized by its , stout body, hump-backed thorax, and broad, membranous wings. These ts are cosmopolitan in distribution, and are abundant in the vicinity of swiftly ng streams, which are the typical breeding habitat of most species. The eggs, sited on grass, twigs, or other objects in the stream, hatch into larvae which h themselves to rocks, logs, or plant stems and leaves in swiftly running r. The larvae require four or five weeks to mature in the summer months. mature larva spins a silken cocoon, within which it pupates. This stage lasts days to about two weeks, and the adult emerges in a bubble of air by which e carried up to the surface of the water. The adults are strong fliers; the females y day and seldom enter buildings to feed. When especially abundant, they only cause great annoyance through their attacks on man and domestic animals, they may cause considerable economic loss by killing livestock. They are also rs of *Onchocerca volvulus*.

Control of black flies through an attack on the immature stages has been difficult use of the inaccessibility of these stages at the bottom of streams. Preliminary rvations have shown that they can be killed with DDT emulsion, and in obi, Garnham and MacMahon eradicated black flies from a 65-square mile area

through liberal use of DDT emulsion in streams. Too high a concentration of DDT will kill fish, and as trout streams are excellent breeding places of black flies, an insecticide must be used with caution. Gjullin and his associates (1949) tried several insecticides in various formulations against blackflies in Alaska, and found that DDT in acetone was the material of choice as it killed the larvae at a concentration of 0.3 parts DDT per million parts of water but was not lethal to rainbow trout at 30 p.p.m. DDT in fuel oil or kerosene was about as effective as the acetone solution, and the authors suggest that this is the most practical formulation. The larvicides are placed in the stream at a turbulent spot in order to insure mixing; a board used as a deflector under the outlet, or the use of multiple outlets will permit better mixing. Many streams in mountainous areas are not accessible by ordinary ground equipment, but the authors showed that a 20 per cent DDT spray applied by airplane at the rate of 0.2 or 0.1 pound per acre was highly effective. The planes flew at right angles across the streams at 50 to 100 feet altitude, and four 100-foot swaths at the 0.2 pound per acre dosage caused all larvae to detach for a half mile downstream.

Residual insecticides may be of some use if applied to vegetation in which adults rest. The dusting of bushes, shrubs, and other vegetation with DDT dust at the rate of 15 pounds of DDT per acre will provide limited area protection. Aerosols and sprays will also kill resting adults.

The new repellents will protect the user from attack for several hours; they may also be used on domestic stock at the rate of about 150 ml. per animal.

**Family Tabanidae.** *The horseflies and deer flies.* The adults are large, robust insects with strong powers of flight. They are active by day and attack man and animals indiscriminately. The larger, darker colored horseflies are associated with animals, and mechanically transmit certain animal parasites such as anaplasmosis and surra, while man is attacked especially by the smaller, more brightly colored deer flies. The latter are responsible for transmission to man of the filaroid *Loa loa* and tularemia.

Most of the tabanids lay their eggs in a packet on leaves or twigs above water at the edges of ponds or streams. The larvae hatch from the eggs and drop into the water, where they sink to the bottom and burrow into the mud. From here during the course of their life, they work their way through the soil away from the water, and eventually come to lie beneath the surface of dry ground. Older larvae of *Chrysops discalis* rise to the surface of the water at night, and are carried by wind and currents towards the shore. Larvae of *T. lusiophthalmus* molt eight times before winter sets in; they hibernate as mature larvae, and in the spring the pupa is produced by the ninth molt. After about two weeks the adult emerges from the pupal case. Although tabanids are usually associated with water, larvae of some species may be found in many purely terrestrial situations. In New York the important pest species *T. quinquevittatus* breeds in moist but not wet soil of pastures and meadows. The strong larvae are predaceous, and feed upon insect larvae, earthworms, and similar kinds of prey.

Control of tabanids is difficult because of the inaccessibility of the immature stages in the soil. Some success has been reported through the use of an airplane to spray oil solutions of DDT at the rate of one pound DDT per acre of stream line; 1 per cent by weight of aluminum stearate added to the spray prolonged

dual effect and increased coverage. Some reduction in horsefly and deer fly abundance has been noted following thorough treatment of hides of range cattle with sprays of DDT, BHC, chlordane, and methoxychlor. Roth and Lindquist (48) were able to trap thousands of ovipositing females of *C. discalis* by smear- a nondrying adhesive on boards set up on end along the shores of a lake. Large numbers of females were attracted to such stakes or other objects when they were placed some distance away from the sedges which formed the natural oviposition site.

**Family Rhagionidae. The snipe flies.** Although not concerned with disease transmission, the snipe flies should be mentioned because a few species are blood-suckers. They somewhat resemble the horseflies.

**The Muscoid Diptera.** This is a large group of *Cyclorrhaphous* flies, and includes several closely related families which are of medical importance; the *Muscidae* (housefly, stable fly, tsetse flies, etc.), the *Calliphoridae* (the blowflies), and *Sarcophagidae* (the flesh flies). In this group are also the ox warbles, the eye bots, the sheep head grub; also, there are two more distantly related families which must be considered, the *Drosophilidae* (fruit flies) and the *Chloropidae* (biting flies or eye gnats). The taxonomic relationships of this large group of flies are complex and difficult; for our purpose it is convenient to consider first the nonbiting forms, second the bloodsucking forms, and finally the species with parasitic habits.

**THE NONBITING FLIES.** The common housefly, *Musca domestica*, may be used to illustrate the general biology of the nonbloodsucking muscoids. This species is cosmopolitan in its distribution, and is represented in much of the Old World by the subspecies *vicina*. The female fly deposits about 100 to 150 eggs in a batch on a suitable breeding medium. A female fly may deposit several to as

Fig. 7-4. Housefly (*Musca domestica*) using proboscis in the act of eating sugar.

Fig. 7-5. Eggs of housefly as laid in a mass.

as 20 or more batches, so that the total output may be over 2,000 eggs. Incubation period varies with the temperature, ranging from 6 to 12 hours. The wedge-shaped larva tapers to the rudimentary head, which is armed with a pair of mouth hooks. There are three larval stages, and it takes about a week for the larva to complete its development. At this time the larva crawls away from its breeding medium to a drier environment; then the larval skin shortens, folds up at the ends, and hardens to form the puparium, which is dark brown in color. Within the puparium pupation takes place and the imago is formed. The pupal period lasts three or four days. When the adult is ready to emerge, the body

fluids are forced into the head, resulting in the formation of a large bubble-like ptilinum which forces off the anterior end of the puparium and permits the fly to escape. The ptilinum then retracts. Copulation takes place on the first day after emergence, and the female may begin to lay eggs on the third day after emergence. The entire life cycle, therefore, under favorable conditions, may require as little as 12 days, and with the high reproductive potential, tremendous fly populations may be built up within a very short time. In temperate regions the flies become most abundant during the warm months of the year; in the tropics they seem to be especially prevalent after rains. Overwintering appears to take place as full grown larvae, but in protected places, such as barns or other buildings where there is some heat, reduced breeding may continue throughout the cold season.

Fig. 7-6. Larvae of housefly.

The housefly, and the related species of blowflies and flesh flies, are of medical importance because of their feeding habits and because of their strong powers of flight, which makes it possible for them to transport mechanically pathogenic organisms from fecal material directly to man or to food about to be ingested. The adults feed upon all kinds of materials in solution or in suspension, which are sucked up through small openings in the large, fleshy labella at the apex of the proboscis, and if the insect is feeding upon feces passed by a diseased person, bacteria and even ameba cysts may adhere to the labella or actually be taken into the gut or esophageal diverticula. When replete, flies have the habit of regurgitating and the vomit droplets may contain organisms that had been ingested and were adhering to the labella. Bacteria may be passed off with the feces; they may also be transported by adhering to the legs or the external surface of the fly's hairy body.

The adult houseflies and blowflies may travel for long distances; this is particularly true of blowflies, which range widely and invade an area in a short time if attractant food and breeding materials become available. Houseflies are not likely to range afar, but remain within the neighborhood of the breeding place unless forced out by population pressure. Thus city dumps, poorly sanitized food processing plants, dairies, etc., may be so highly infested that they will be the source of houseflies for an entire community.

The characteristic breeding places of the housefly are deposits of fecal material. Manure pile has always been the principal source of houseflies in rural areas, other decomposing organic material, especially high protein stock feed allowed to become moist, may also support breeding. Blowflies are essentially scavengers, feeding in decomposing carcasses, but they will breed as well in other decomposing material of animal origin. Important sources of houseflies, blowflies, and related species in urban areas are garbage dumps, garbage cans, dog feces, scraps of food and debris about restaurant loading platforms, greased soil around fat-rendering plants, abattoirs, privies, and stables. The importance of understanding the nature of the breeding places in areas where fly infestation is a problem, lies in the fact that treatment of buildings with DDT or other residual sprays will kill off only a small percentage of the flies being produced.

The resting habits are another aspect in the biology of the adult flies which is of importance in control procedures. The flies are inactive at night, and treatment of nocturnal resting places may be a highly effective means of attack. Scudder (1919) observed that in summer, houseflies as well as blowflies rest out of doors at the feeding and breeding places, on twigs at the end of low-hanging branches, on weeds, fences, wires, and edges of buildings, in locations where there is protection from the wind, and above ground level but not above 15 feet in elevation. In cooler weather, houseflies prefer to rest inside buildings, while the blowflies continue to rest out of doors. In buildings, houseflies rest on edges of projecting boards, eaves, and other prominences.

Disease organisms which can be transmitted by the housefly and its nonbiting relatives are those which are picked up by the insects in the dejecta, or in blood from wounds or exudations from sores and mucous membranes. In unsanitary surroundings, particularly under military or internment camp conditions, where large numbers of flies moved freely between unprotected food and uncovered fecal deposits, outbreaks of typhoid and dysentery have been attributed to the transfer by flies of bacteria from the feces to the food. Watt and Lindsay (1948) reported a significant reduction in the incidence of *Shigella* infections as a result of thorough residual treatments. It has also been reported that intensive malaria control campaigns through the use of DDT have not only reduced malaria and the mosquitoes, but have reduced intestinal infections and infant mortality, presumably through the destruction of flies. Recent work has shown that poliomyelitis virus, deposited with the feces, may be picked up by flies. Naturally infected flies have been found in localities where poliomyelitis epidemics were occurring. *Entamoeba histolytica* may be fly-borne under suitable conditions. Fly transmission of all of these infections is more or less accidental, and can take place only where lack of sanitation permits high fly densities and access to feces. The species of *Chloropidae* belong-

Fig. 7-7. Puparium of housefly.

ing to the genera *Hippelates* and *Siphunculina* may become extremely annoying by crawling over the skin to feed upon the sweat and exudations from sores and mucous membranes. The mouth parts are armed with a specially adapted rasping apparatus to better enable the insect to obtain its food. These small gnats thus are capable of mechanically transmitting eye infections, and have been associated with outbreaks of pinkeye, "Naga sore," and epidemic conjunctivitis; they have also been shown to transmit yaws.

In the control of the housefly and its allies, great benefit has resulted from the use of DDT and other residual insecticides. DDT, applied at the rate of 200 mg. per square foot, remains toxic to flies for three months or more, provided the surface is protected from weathering, accumulation of dust, and the like. Scudder (1949) recommends a 2.5 per cent spray on rough unpainted surfaces such as are found in barns, a 5 per cent spray on painted or plaster surfaces, and a 7.5 per cent spray on smoothly finished surfaces in restaurants and homes. The idea is to apply the spray so as to thoroughly wet the surface without run-off.

Scudder also emphasizes the importance of treatment of the nocturnal resting places out of doors, as the flies are inactive for several hours and hence the residual insecticide would be much more effective than it is indoors on the surface of diurnal resting places where the active flies come into contact with it only briefly. The wettable powders are more suitable for use in spraying outdoor resting places, as they are not so harmful to vegetation as are oil solutions, and appear to adhere better to vegetation. It has also been found that the addition of an adhesive consisting of 10 per cent pine gum rosin to the 25 per cent DDT-xylene emulsion concentrate will increase the duration of an emulsion residual on exterior surfaces.

Benzene hexachloride, chlordane, methoxychlor, chlorinated camphene, DDT and dieldrin have all been found to be more or less effective as residuals for fly control. However, there is serious doubt as to the continued effectiveness of the chlorinated hydrocarbons because of the development of resistant strains of flies.

Space sprays may be used by the householder for temporary relief. They may also be used in community fly control; in this case whole areas are sprayed from an airplane or fogged with a ground aerosol-producing machine. Kruse (1948) states that satisfactory urban control without staining damage may be obtained with sprays having a minimum mass diameter of 200 microns applied from an airplane flying at 100 to 150 feet altitude. He recommends a 30 per cent solution of DDT in Velsicol AR-60, applied at the rate of 0.5 pound of DDT per acre.

Regardless of the effectiveness of various insecticides in reducing fly density and even in reduction of enteric infections, experienced observers have been emphasizing the importance of *sanitation* as the real solution to the fly problem. Elimination of fly breeding in city garbage dumps, which may produce enough flies to infest an entire municipality, could be achieved by proper sanitary garbage disposal methods. Other recommended measures are the picking up of dog feces by individual dog owners, provision of adequate garbage containers by householders, periodic cleaning of the containers and wrapping of garbage to prevent accumulation of garbage sludge at the bottom of the cans, and elimination of privies. W. outlines the following steps in a program designed to control fly-borne diseases:

1. Preliminary survey of the problem area to determine whether flies are actually involved in dissemination of disease.

2. Planning of basic sanitation methods, including garbage disposal, disposal of feces, proper care and feeding of domestic animals, and supervision of waste disposal from industries.

3. While the sanitation program is getting under way, the use of insecticides to reduce the active fly population. This may be effected by the use of residual sprays, discussed above, or through the use of space sprays, which, in large operations, may be sprayed from airplanes or by means of the ground spray machines. During the period larvicides, such as orthodichlorobenzene, may be used, but steps must be taken promptly to eliminate the conditions which permit breeding in the breeding areas. Watt concludes that the major emphasis should be "on an enduring preventive program rather than a temporary palliative measure."

For control in rural areas, proper *manure disposal* is essential. Under certain circumstances manure may be burned, stored in special vats until it has matured, stored in compact heaps covered over with a tarpaulin or tarred paper. Manure is a necessary fertilizer, and ordinarily cannot be destroyed; however, as Scudder points out, the manure pile is "incompatible with modern dairy sanitation." Daily removal would help if it were possible for the farmer to accomplish this; temporary storage of three or four days will probably not reduce breeding markedly. If manure must be stored, some reduction in breeding is obtainable through the use of larvicides. Those used have included hellebore at the rate of 0.5 pound per bushels of manure, and powdered borax at the rate of 1 pound to 16 cubic feet of manure. More recently, the chlorinated insecticides have been used, but Bruce and Hoyer (1950) recommend the use of larvicides not chemically related to a residual which may be employed in the same area, in order to delay the building up of resistance of the insects. An emulsion containing 2 to 4 per cent chlordane, applied at a rate of 50 to 100 mg. of the toxicant per square foot of surface, is said to give good results. Good kill of larvae has been obtained through the use of 20 gm. of dichlorobenzene or 25 ml. orthodichlorobenzene per square foot of surface. Repeated in two to four days, these dosages may be reduced respectively to 15 gm. per bushel. These materials are also good ovicides. Larvicides may also be applied to garbage, and cadavers. If garbage is fed to hogs, chlordane and similar compounds cannot be used.

Various types of fly traps may give some local relief from annoyance; screening of houses is an important protective measure; protection of foods by screens, nets, and the like is highly desirable.

**THE BITING MUSCOID FLIES.** The bloodsucking *Muscidae* include several important parasites of domestic animals, such as the horn fly and stable fly or "dog fly." The latter breeds in decaying vegetable matter such as that found at the bottom of manure racks, accumulations of seaweed, and the like, and at times breeding may be so heavy that the fly density reaches outbreak proportions. The insect attacks man and may cause extreme annoyance. Fortunately, this ubiquitous fly is not a carrier of organisms pathogenic to man. Related to the *Muscidae* are the commensal parasitic *Pupipara*, which live upon mammals and birds. The wingless sheep tick "tick" is a member of this group.

The most important of the biting *Muscidae* are the *tsetse flies* of tropical Africa, which are vectors of the trypanosomes which cause Nagana in animals and sleeping

sickness in man. They are somewhat larger than the house fly, and are recognizable by the bayonet-like proboscis projecting from the lower margin of the head. The life cycle of the tsetse flies is especially interesting in that the larva undergoes its develop-

Fig. 7-8. Stable fly (*Stomoxys calcitrans*).

Left, adult fly; right, head showing proboscis. (After Brues.)

ment entirely within the body of the female. One larva is matured at a time, and the female may produce a total of 8 to 10 larvae. The larvae are dropped in a suitable sheltered habitat, where the soil is dry, shaded, and loose enough so that the larva can burrow through it. Within a few hours after having been dropped, the larva has

penetrated into the soil for a depth of an inch or more and then pupates. The adults also require a suitable habitat in which to reside where they will be protected from heat and drying; larvae and adult requirements are found, depending upon the species, within certain types of bush or thicket. The bush in which survival is possible through the unfavorable hot, dry season is recognized as the "winter habitat" of the flies; during the rains when the vegetative cover increases, the flies are able to spread out into areas which ordinarily would be unsuitable. Areas

Fig. 7-9. Tsetse fly (*Glossina palpalis*).

infested with the flies are known as fly belts; these fly belts contract or expand with the seasons. The fly belt of *Glossina palpalis* and *G. tachinoides*, the important vectors of Gambian sleeping sickness, is a narrow one comprised of the wooding forest along the banks of streams or the shores of lakes. *G. morsitans* and *G. swynnertoni*, the important vectors of Rhodesian sleeping sickness and Nagana, are found in the open savannah country, where, although indifferent to the presence of water, they

and in the shelter of certain types of vegetation. The fly belts inhabited by the species may be very small or very extensive, covering thousands of square miles. Within the true habitat breeding occurs, but young, recently fertilized females driven by hunger out of the dense cover of the true habitat into more open country, where better visibility enables them to find animals upon which to feed. These hungry females will also attack man, although the game species, such as *G. morsitans*, prefer to feed upon animals. *G. palpalis* and *tachinoides*, in their riverine habitat, are more closely associated with man and are able to exist with only man and domestic animals as sources of blood.

Because of the advanced larviparous mode of reproduction, control of the tsetse flies has been difficult but, nevertheless, considerable success has been attained in the control of the human trypanosomiasis at least. Aside from the use of chemotherapy and chemoprophylaxis and removal of populations from endemic zones, the measures employed that have been most successful are the clearing of vegetation from the true habitat, catching of adults, and destruction of game. Clearing operations may be limited to small protective clearings at river crossings, near villages, trading sites, and the like to prevent contact between the riverine tsetse and people who must enter this habitat, and aggressive clearings, by which tsetse are eradicated from large blocks of country by drastic removal of vegetation. Through discriminative clearing of only the vegetation forming the true habitat, even the widespread savannah species may be attacked effectively; in East Africa, clearing, resettlement, and farming operations combine to free large tracts of country from *G. morsitans* and its allies. A combination of block clearings along rivers and routine handling by teams of fly boys working through the uncleared areas along paths parallel to the streams has been found to reduce greatly the chances of infection with Gambian sleeping sickness. Adult tsetse hunt mainly by sight, and some species can be fooled with the rudest of decoys; many types of traps, of which the best known is the Harris trap, have been devised to catch adults. The systematic destruction of game, which serves as the source of blood for the savannah-inhabiting species, has been credited with freeing large areas of East Africa from *G. morsitans*. *Callidipes* is less affected by game destruction, as it will feed upon small animals and insects, while the riverine *G. palpalis* and *tachinoides* have been shown to be capable of survival in West Africa in areas in which game has long since been exterminated. Recently, control has been attempted through the use of DDT and benzene hexachloride; these insecticides were sprayed from airplanes, or applied to the vegetation of the habitat, or applied to the hides of cattle. Great reductions in fly densities occurred in the treated areas, but up to the present time the use of these insecticides has not given the hoped-for results.

**Myiasis.** The term myiasis refers to the parasitism of man and animals by fly larvae. All stages in the development towards parasitism may be observed among the *Corrhaphous* fly larvae. Most of them are free living, breeding in decomposing vegetable or animal matter; others occasionally invade the digestive or urinary tract accidentally, where they may exist for a short time; and still others infest wounds where they feed upon exudates and necrotic tissues. The latter are larvae of blow-flies and flesh flies, which ordinarily breed in decaying carcasses. Some of the blow-flies also breed in the wool of sheep and so cause serious economic loss. The true

or obligate parasites invade living tissues of man and animals, and are found either beneath the skin, in wounds or body openings, or in the digestive tract.

Larvae which live beneath the skin cause cutaneous myiasis. The ox warble (*Hypoderma*) cause large cysts to form on the backs of cattle, and in each cyst a single larva completes its growth. In tropical America, similar cysts are produced by the larvae of *Dermatobia hominis*, which attacks both man and animals. The female of this interesting insect glues its eggs in small packets usually to a mosquito when it has captured. The larvae are carried to the host by the mosquito when it seeks a meal of blood. In Africa, the eggs of the tumbu-fly, *Cordylobia anthropophaga*, are deposited in sandy soil contaminated with excreta of animals; the newly hatched larvae attach themselves to animals walking or resting on the soil, and they then burrow beneath the skin where they complete their growth. It has been shown that infected animals acquire an immunity to reinfestation by *C. anthropophaga*; in immune animals, the larvae are killed by a precipitate which forms around the larvae and in the gut. The antigenic substance appears to exist within the excreta of the larva. Species of *Wohlfahrtia* deposit small larvae on the skin of the host; they quickly penetrate and produce lesions beneath the skin in which they grow. Man is frequently attacked and serious damage may result from invasion of the eye, ear, or nasopharynx. It is said that in the range of the Palearctic species, *W. magnifica*, it is dangerous to sleep out of doors in the summer months during the middle part of the day when the adults are active.

Of the cavity and wound myiasis-producing species, *Cochliomyia americana*, the primary screw worm fly of the New World, is of great importance. Females are attracted to abrasions in the skin, caused by scratches, tick bites, and the like, and lay their eggs in packets at these sites. The larvae burrow through the abrasion into the living flesh. Untended infestations are fatal, and large losses of stock are suffered by farmers and ranchers. The permanent range of this species includes the tropics and subtropics but during the summer, through migration and importation of infested animals, it invades the northern states, where serious outbreaks occur from time to time. Occasionally, man is attacked, and extensive damage or even death may result from the invasion of the nasopharynx or other cavities. In the Orient and Ethiopian tropics, *Chrysomya bezziana* has similar habits and is a common cause of myiasis of man, being found in ulcers, the ear, mouth, orbit, vagina, and the like. *Oestrus ovis* females deposit small larvae in the nostrils of sheep; the larvae migrate to the frontal sinuses where they complete their development. The fly also attacks man at times, and may place the larvae in the eye.

Intestinal myiasis is caused in horses by species of *Gasterophilus*, the horse bot. Eggs are glued to the hair of the animal, the larvae find their way to the mouth, and eventually reach the stomach and duodenum where they attach to the mucosa. When mature, they pass out with the feces, and pupation occurs in the ground. In all the species discussed above, mature larvae leave the site of their development on the body and drop to the ground, where pupation occurs. After a few days or weeks, depending upon the weather and the species, the adults emerge. Adults of the oestroid flies (ox warbles, horse bots, etc.) do not feed; their mouth parts are vestigial. However, although they neither bite nor sting, horses and cattle show an instinctive dread of these insects, and may make violent efforts to avoid contact with them.

According to a number of reports in the literature, larvae of blowflies, flesh flies, eflies and anthomyids will cause temporary myiasis in the intestine or bladder. Larvae apparently gain entrance to the intestine through ingestion of foods containing larvae or eggs, or by way of the anus, and to the bladder by way of the uretra. Stool samples frequently contain fly larvae but most of them undoubtedly result from deposition of eggs after the stool has been passed. Rat-tail maggots, of the genus *Eristalis*, breed in water heavily charged with organic matter; they sometimes are ingested accidentally and cause gastric upsets. Other temporary invaders of the alimentary canal are larvae of the soldier fly, *Hermetia illucens*, and of the house shipper, *Piophilha casei*.

A few larvae are external parasites. In Africa, the Congo floor maggot, *Auchmyia luteola*, lives in the dirt of floors of native dwellings and comes out at night to seek blood of available hosts.

For treatment of animals infected with the primary screw worm fly, the U. S. Department of Agriculture recommends "Smear 62," the ingredients of which are as follows: diphenylamine, 3.5 parts; benzol, 3.5 parts; turkey red oil, 1 part; and carbon black, 2 parts. Spray and dips containing DDT and benzene hexachloride promise of being highly effective in controlling sheep wool myiasis.

A recent summary of the Diptera which produce myiasis in man is that of James (1970).

**Order Siphonaptera. The fleas.** The fleas are small, wingless ectoparasites of birds and mammals. They are compressed laterally, and the body is clothed with backward-pointing bristles and spines. The powerful hind legs permit the flea to jump for six inches or more into the air; presumably, this aids the insect in reaching its host. Both males and females are bloodsuckers, and the fleas are responsible for the transmission of plague and murine typhus. Some species remain on the host almost constantly, while others do so only for purposes of obtaining blood, and return to the environment between blood meals. The host-parasite relation is not strict, although most fleas have a favored host species or a few species. The indifference exhibited by fleas to the species of host which furnishes them with blood is of great importance to the epidemiology of the flea-borne diseases, for it makes it possible for the insects to convey infections from their rodent hosts to man, and the vector role is determined not only by the ability to transmit the disease organisms as it is by the association between the fleas, hosts, and man. Rat fleas readily leave sick and dead rats to feed upon man.

Eggs are laid by the female while she is on the host, in which case they even fall to the ground, or while she is in the nest or habitation of the animal. Eggs are produced singly or in small clusters of a dozen or two; and the female flea, under favorable conditions may live for several weeks to a year or more, lay a total of several hundred eggs. The eggs hatch in two days to two weeks. The worm-like larva feeds upon particles of organic matter which it finds in the debris of the host's habitat, such as dried feces, nest material, bodies of dead insects, and blood seems to be essential for proper growth, and the main source of this food appears to be the fecal pellets of dried blood passed by the adult fleas. Blood alone is not a suitable diet for the larvae; micro-organisms are probably necessary to furnish vitamins of the B group. The larvae require periods of from about two weeks to as much as four or five months to complete their development. Mature larvae

spin a cocoon; within the cocoon the larva pupates. Before pupating, the larva may go through a prolonged period of resting within the cocoon; the pupa itself may stay for only a week or for a much longer time, and the adult flea may remain quiescent within the cocoon for long periods when no hosts make their appearance. The total length of time spent in the cocoon has been observed to vary from seven days to over a year. There is, therefore, a great deal of variation in the rapidity of the life cycle; it may be completed in two or three weeks, or it may require considerably more than a year. It would appear that this is of survival value to the flea; as the larvae are free living and pupation occurs in the habitat, the great staggering in the appearance of the adults is insurance that at least some of them will contact the host. From Sharif's studies it would seem that the larva, too, is dependent upon the presence of the host, as it requires the blood passed by the adult fleas which in turn obtain their food from the host. Without it, the larvae go through a period of suspended development, which again is a mechanism for preservation.

Climatic factors have a profound effect upon rapidity of development; high temperatures may hasten the life cycle and high humidity will increase the longevity of the adult, but rainfall is detrimental to the larvae as they prefer a relatively dry breeding medium. It has been suggested that the reason for the high flea infestation of burrowing mammals and birds is that the burrows furnish an environment protected from severe climatic conditions.

Some of the important species of fleas are as follows:

*Pulex irritans*. The human flea. This flea has a cosmopolitan distribution and man is the favored host, although it will attack a wide variety of wild and domestic animals. Pigs are especially attractive, and exceedingly heavy infestations of pig sties may be built up. Such infestations may also develop in and around houses, lumbering camps, and other dwellings; breeding then takes place in the litter under and about the buildings. Adults may even be abundant in the lawn around the house.

Fig. 7-10. The human flea (*Pulex irritans* Linn).

*Xenopsylla cheopis*. The Oriental rat flea or tropical rat flea. Through commerce this flea has attained a tropicopolitan distribution, and it is also widespread in temperate zones. In the United States it was first reported from seaports, but more recently it has been shown to be present in many cities from the north central states. Although a tropical species, it is capable of surviving the winter in these northern

des; presumably the climatic conditions within the protected rodent's burrows in suitable during the cold months. It is the most important of the rat fleas, as the species primarily associated with flea-borne diseases. The adults remain on host for most of the time, and when the rat dies the fleas readily attack another

Fig. 7-11. The Indian rat flea (*Xenopsylla cheopis* Rothsc).

which, because of the close association between man and rat, is apt to be man. There are several other species of *Xenopsylla*, of which the tropical *X. astia* and *X. asiatica* are also associated with domestic rats.

*Xenopsylla fasciatus*. The rat flea of the north temperate climates. The effect of climate upon this species and *X. cheopis* is brought out by the study of Davis and others in Baltimore, where *X. cheopis* is the predominant flea on rats during the warm months while *N. fasciatus* is rare; during the winter months *X. cheopis* is rare, and *N. fasciatus* becomes common.

Fig. 12-13. The common rat flea of Europe and North America (*Ceratophyllus fasciatus* Bosc).

*Ctenocephalides canis* and *C. felis*. The dog and cat fleas. Although primarily associated with the dog and cat, respectively, both species will attack man readily as well as other animals. They are common pests in houses.

*Leptopsylla segnis*. The European mouse flea. This species now has almost a cosmopolitan distribution; it is found on domestic rats and mice.

*Spilopsylla gallinacea*. The stick-tight flea of poultry. Rats, dogs, and other animals as well as man, are also attacked. The adults remain attached to the host for long periods of the mouth parts.

*Tunga penetrans*. The chigoe flea. This species is widespread in tropical America and Africa. It has been reported from New Orleans and southern California. The females burrow into the skin and here swell up to about the size of a pea. The males are ejected through the opening in the skin. In favored areas of sandy soil, the flea may be very abundant, and cause great annoyance to barefooted natives especially. Secondary bacterial infections may set in with serious consequences which may require amputation. Obermayer (1943) discusses the treatment of the infestation and if suppuration has not yet taken place, he recommends thorough cleansing of the affected part with soap and water and extraction of the flea with a blunt, heated needle. If the whole flea is not removed, bacterial infection will result. If suppuration has already set in, following removal of the flea the site of infestation should be cleansed with phenol and alcohol, and dressed with a 5 per cent sulfathiazole-sulfadiazine cream. Contact of the bare skin with infected soil should be avoided and the best prophylactic measure is the wearing of shoes.

A number of species of fleas are associated with wild rodents, and are of importance in that they maintain sylvatic plague among these hosts (see page 403).

Fig. 7-13. A squirrel flea (*Hoplopsyllus anomalus* Baker).

**Control of Fleas.** The adult fleas infecting dogs and cats may be killed by dusting the animal with derris powder containing at least 0.5 per cent rotenone or 5 or 10 per cent DDT dust.

Almost all the fleas on wild rats may be killed by dusting the burrows and runways with 5 or 10 per cent DDT. This is a means of typhus and plague control. Macchiavello describes how an outbreak of plague at Tumbes, Peru, was stopped four days after the first application of DDT dust. There was a reduction of over 90 per cent in the flea infestation on rats. A cyanogas foot pump may be used to blow the dust into the burrows and other enclosed spaces suspected of being nesting or harboring places for rats. Dust may also be placed at the entrance of the burrow in order to insure maximum contact of the rat with the DDT. A hand shaker may be used to treat open rat runways. Rats running through treated burrows or runways will pick up sufficient DDT to kill their fleas.

Active adult fleas, as well as the larvae breeding in and about dwellings and animal shelters, may be controlled by spraying with a 5 per cent solution or emulsion of DDT or dusting with a 10 per cent DDT dust. In houses the dust should be applied beneath as well as on rugs. All floors and the basement should be treated.

at the same time the dust should be used on household pets. The various residual sprays used in buildings should prove to be highly effective in eradicating flea infestations. Dimethyl phthalate, Rutgers 612, and indalone will give protection against fleas for two hours or more.

**Order Hemiptera.** The order Hemiptera comprises the true bugs. It is a very large order, and contains many insects which are agricultural pests. The bugs have piercing-sucking mouth parts, and some families have become predaceous on other insects. The bloodsucking species are found in the subfamily *Triatominae* of the family *Reduviidae*, and in the family *Cimicidae*.

Some important species of the *Triatominae* ("cone nose bugs" or "kissing bugs") are *Panstrongylus megistus* in Brazil, *Triatoma dimidiata* in Central and South America, *T. infestans* in western South America, *Panstrongylus geniculatus* in Guyana and South America, *Triatoma protracta* in western United States, and *Triatoma prolixus* in South America. The *Triatominae* have primarily an American distribution, but one species, *T. rubrofasciata*, is tropicopolitan. A few other species are also found in the Old World tropics.

The species of *Triatominae* are associated with certain animal hosts, such as rats, armadillos, bats, and other wild and domestic animals. Some of the species will attack almost any animal. In Central and South America, a number of the species, especially *M. megistus*, *T. infestans*, and *R. prolixus* live in the thatch roofs and walls of man's habitations. In the crevices of the walls and roofs the insects find suitable hiding places, where they remain during the daytime. At night they emerge from their retreats to feed upon the inhabitants of the house, and appear to show no preference for man, dog, or other domestic animals about the premises. The domestic animal reservoirs of *trypanosomes*, therefore, become of considerable epidemiological importance.

The life cycle of the *Triatominae* ordinarily requires about a year for its completion. The adult bugs, which possess wings and are capable of flying into houses, live for several months, during which time a number of blood meals are taken. Females deposit several batches of eggs, which may total several hundred. The eggs are deposited in the hiding places, and usually are glued to the substratum. Depending upon temperature, they require three or four weeks to hatch. There are immature or nymphal stages, and the total period of nymphal development lasts over several months. Each nymphal stage requires at least one full meal of blood before it can moult. The fifth nymphal stage moults into the adult.

The importance of the *Triatominae* as pests and as vectors of *Chagas' disease* is directly related to their association with man, and particularly with their habit of invading the rude dwellings in rural Mexico, Central and South America. Permanent control would involve the destruction of infested huts, preferably by burning, and substitution of these by well constructed, tight dwellings in which the bugs would have no harborages. As it is obvious that such a program is dependent upon social and economic progress, reliance at present must be placed upon the use of insecticides. The new residual sprays have shown much promise. In Chile, Neghme and his co-workers report 90 per cent control of the bugs for three months in several villages following the application of DDT. However, DDT is not the ideal insecticide, as complete eradication was not possible except in a few houses with very low initial infestations. Dieldrin hexachloride appears to be superior to DDT, but it must be used in high

concentrations of 1 or 2 gm. per square meter of surface. It remains effective for three months or more. It should be applied especially to cracks and crevices in walls, the thatch roof, beds, and all other possible hiding places. The possibility of development of strains of bugs resistant to the halogenated compounds through widespread use of the residual insecticides must be kept in mind. Pyrethrum may be used as a space spray; it will drive the insects out of their hiding places, but has no residual effect.

The *Cimicidae*, or *bedbugs*, are completely wingless. There are two species which attack man: *Cimex lectularius*, the temperate bedbug, and *C. hemipterus*, the tropical bedbug. Between them they infest all parts of the world inhabited by man. These bugs live in cracks and crevices in man's habitations, particularly in sleeping chambers, and they also infest animal shelters. During the day they remain hidden within their shelters, but at night they emerge to feed upon man or any warm-blooded host that may be available.

Fig. 7-14. The bedbug.

blooded host that may be available. The adult bugs are capable of living for months, even when starved. They take blood at frequent intervals, and the female deposits a number of small batches of eggs. Several hundred eggs may be deposited eventually by the female in the hiding places, where they are glued to the substrate. The eggs hatch in a week or two, depending upon temperature, and there are five nymphal stages, each one of which requires a full meal of blood. Three or four days may be spent in each of the nymphal stages under suitable conditions of temperature and availability of hosts, but at low temperatures or when hosts are not available the nymphs may live for weeks or months. Under optimum conditions the bugs complete their life cycle in about a month, and there may be several generations a year.

Control of bedbugs has been a difficult problem in past years because of the difficulty in getting at the insects in their hiding places. Superheating and hydrogen sulfide fumigation were perhaps the best measures. The residual insecticides are now known to be especially effective against bedbugs. The insects must crawl out of their hiding places in order to reach their hosts at night, and a barrier of a residual insecticide

exterminate them in the treated premises. A 5 per cent residual spray of DDT is perhaps the most effective, but a 10 per cent DDT dust may be used where it is possible to spray. The spray should be applied to mattresses, bed springs and heads, and to the walls, particularly around the baseboards. Inspection will find the most likely hiding places of the bugs, and the spray or dust must be applied especially at them.

**Order Anoplura. The lice.** There are two kinds of lice, the *Mallophaga* or bird lice which do not suck blood, and the bloodsucking *Anoplura*. The latter infest a variety of animals, and three forms are found on man: the body louse, *Pediculus humanus* (often called *corporis* or *vestimenti*) the head louse, *P. capitis*; and the crab louse, *Phthirus pubis*. The body lice and head lice are different populations or subspecies of a single species.

Fig. 7-15. *Pediculus humanus* var. *Corporis*.

The life cycles of these lice are essentially the same. The eggs of the body louse are found in the clothing, and are glued to the cloth especially along seams and in folds. The gregarious females tend to lay their eggs where other eggs have been deposited. A female will lay from one to a dozen eggs a day, and under normal conditions a female may produce a total of 275 to 300 during the course of her life of a month or two. When kept continuously on the body, the following developmental periods for the various stages in the life cycle have been observed: egg, eight days; first nymph, two days; second nymph, two days; and the pre-reproductive period, one day. The total cycle, therefore, requires 16 days. Pairing occurs within a few hours after the adult stage is reached. The rapidity of this cycle depends upon temperature, and each of these stages may be considerably delayed in lice in clothing that is removed from the body. Under these conditions, hatching of eggs may be delayed for as much as 24 days, while the active stages may survive for a week or 10 days even when they are unable to obtain food.

All the active stages of lice require blood; they take small meals at frequent intervals. In the process of feeding, small denticles at the mouth opening anchor the louse to the skin; needle-like stabbers then pierce the tissues and cause a flow of blood. The sucking lice are extremely host specific; a given host has only its own species of lice. Recently, however, strains of human lice have been adapted in the U. S. Department of Agriculture laboratories to exist upon rabbits.

*Body lice* are most numerous in the layers of clothing next to the body. Once an infestation has set in, the chief factor influencing density is the changing of undergarments. McCleod and Benson state that infested persons "very soon become victims of their own habits." The louse population may build up very rapidly unchecked, and occasionally an individual may possess thousands of the insects in his clothing. Scratching and restlessness on the part of heavily infested persons may cause the lice to wander about and reach the outer surface of the clothing, from which they may be readily transferred to other persons. Thus, in crowded tenement houses, prisons, refugee camps, and the like, lice may spread rapidly through the entire population. Under unsettled conditions or times of war or disaster, when prisoners, refugees, or troops are unable to change clothing or bathe regularly, the body louse infestation may increase to the point where epidemic typhus, trench fever, and relapsing fever break out. This is particularly true during the winter, when bathing is made more difficult by the cold weather.

Lice are sensitive to temperature, and move away from a person with a high fever, or from a cold cadaver. Thus, persons working with the sick and dead are most apt to encounter infected lice. Lice are also disseminated by means of clothing, bedding, and other articles used by infested individuals. In times of peace, the majority of louse infestations will be found among the poorer classes of people among whom lack of facilities reduces the frequency of bathing, and the changing and laundering of clothing.

The *head lice* live in the hair of the head. The eggs are glued to the roots of the hair. The total developmental period requires about 17 days. Buxton (1941), who made a study of head louse populations in crops of human hair, noted that the numbers of lice were greater in heavier crops of hair, that women were more heavily infested than men, and boys more heavily infested than adult males. Occasionally there may be over a thousand lice on the head, but the usual infestation is much smaller than this, numbering 10 or less individuals. The limitation in size is due not only to grooming and conscious delousing efforts on the part of the host, but also to some natural checks. In small populations, one sex predominates. Progeny of a single female are often almost all of one sex, and an infestation started by a single immigrant female would thus be unisexual and unless supplemented by additional immigrants of the opposite sex, the infestation would be short lived. If the infestation becomes established successfully, so that the lice increase to 100 or more individuals, males outnumber the females. By their frequent and violent copulations the males greatly shorten the life of the females, which causes the oviposition rate to drop.

The *crab lice* ordinarily live in the hair of the pubic region, but they may also be found in the arm pits and even in the eyebrows and eye lashes. They may be generally distributed over the body of a hairy person. This species is thought to

inated mostly by coitus, but infestations may also be acquired by other means. Children with eye-lash infestations unquestionably are infested by lice wandering from infested parents. Pubic hairs to which nits are attached are often removed from the body, and larvae hatching from these eggs may be picked up from clothing, toilet seats, wrestling mats, and the like. Nuttall observed a life cycle that required 22 to 27 days for completion.

In addition to being vectors of *epidemic typhus*, *relapsing fever*, and *trench fever*, lice are directly responsible for irritations and for a skin condition known as "vagabond" disease, which is characterized by rough, thickened, and deeply pigmented skin. Severe skin reactions are considered by Peck and others (1943) to be due to development of hypersensitivity to the louse feces. These authors observed that persons without previous contact with lice, the bites caused only minute, noninflammatory and nonpurpuritic points which were flat with the skin. The hemorrhage was minute. Hypersensitivity developed after 7 to 10 days of daily exposure, and inflammatory reactions set in. At the site of the bite, rupture of the capillaries caused a purpura; the skin became red, edematous, and studded with vesicles. This condition subsided in five to eight days, leaving a brownish pigmentation. A general feeling of illness may be produced by large numbers of the insects, with dull headache, low fever and pains in the joints.

From Soper, Davis, Markham, and Riehl, *Am. J. Hyg.*, 45:305, Fig. 16, 1947.

Fig. 7-16. Seventh step in dusting an individual.

The *control of lice* was vastly improved during World War II. Instead of employment of elaborate delousing stations, which utilized steam, dry heat, or fumigants for destruction of lice in clothing, louse powders were developed which could be applied to the clothing and body and eradicate an existing infestation as well as protect against reinfestation without the necessity of bathing and sterilization of clothing. Some success was obtained with powders containing derris and naphthalene (the AL 63 powder) and pyrethrum plus a synergist and antioxidant (MYL powder), but these were replaced by DDT when the latter became available. A 10 per cent DDT powder in pyrophyllite may be applied liberally by the individual user from a sifter-can container to the underwear and the inner surface of the outer garments. The powder should be distributed by hand, with particular attention being paid to the seams. For treatment of large groups of people, the powder is blown by means of a hand duster between the skin and clothing and between the layers of clothing. About one and one-half ounces of powder is required per person. Mass treatment with louse powders is credited with stopping epidemic typhus in Naples in 1944 and in the Belsen concentration camp in 1945.

Where lice have become resistant to DDT, the 1 per cent lindane powder may be substituted for DDT.

The *head louse* also may be controlled by applying the 10 per cent DDT powder to the hair of the head. A second application after a week or 10 days may be necessary to kill lice hatching from eggs subsequent to the first treatment. Successful control of head lice has been reported with the following formula:

Phenyl cellosolve . . . . .	5 parts
Ethanol . . . . .	47.5 parts
Water . . . . .	47.5 parts
Perfume to give a slight pleasant odor.	

The patient while being treated holds a towel to his forehead so that none of the lotion can run into the eyes. The hair is wetted thoroughly with the lotion, rubbed into the scalp, and the excess wiped off. This material kills eggs as well as the active stages. Busvine and Reid report highly successful head louse control through the use of 0.2 per cent benzene hexachloride in coconut oil.

The DDT powder is *effective against the crab louse*; it should be rubbed into the hairy parts of the body, so that it reaches the base of the hairs. The NBIN formula was developed as a combination treatment for lice and scabies.

NBIN formula:

Benzyl benzoate (scabicide) . . . . .	68 parts
Tween 80 (emulsifier) . . . . .	14 parts
Benzocaine (ovicide) . . . . .	12 parts
DDT (lousicide) . . . . .	6 parts

The DDT and benzocaine are dissolved in the benzyl benzoate; the Tween 80 is then added to make an emulsion concentrate. For use on the body, one part of the concentrate is added to five parts of water. For control of head lice, about 20 ml. of the emulsion may be applied to the head, care being taken to protect the eyes. A single treatment will eradicate lice from the body; eggs as well as the active stages are killed. The emulsion may be applied by means of a sponge or it may be sprayed upon the body. All parts of the body should be treated, and about 50

person are required. Following treatment, bathing should be delayed for 24 to 48 hours.

**Class Arachnida. Superfamily Ixodoidea (the ticks).** There are two families of ticks, the *Argasidae*, or soft ticks, and the *Ixodidae*, or hard ticks. The soft ticks are vectors for *endemic relapsing fever*, and the hard ticks are vectors of *rickettsias*, *typhus*, and several diseases of animals.

The ticks are rather degenerate parasites. The body, which in unfed ticks is compressed dorsoventrally, shows no segmentation; the head or capitulum is retracted and bears an elongate hypostome which anchors the tick to the flesh of the host and two rod-like chelicerae which are used for penetrating the host's tissues, and two pairs of hollowed palpi which are presumably sensory and also form a sheath for the mouth parts. There are four pairs of legs in the nymphal and adult stages, but the larvae have only three pairs. Eyes, when present, are simple ocelli situated on the sides of the body at about the level of the second pair of legs. Hard plates on the dorsal and ventral surfaces of the body give the name of "hard ticks" to the *Ixodidae*. The leathery posterior portion of the body of the female hard tick is distensible of great distension to accommodate the large meal of blood. With a few exceptions, all stages of the ticks require blood.

The life cycle of the soft ticks may be illustrated by those of *Ornithodoros* *taeniophorus*. It lives in native huts, where it feeds upon man and domestic animals. The eggs are deposited in hollows burrowed by the female in the sand or soil of the floor of the hut. The incubation period requires 8 to 25 days. The larva is unable to feed while still in the egg shell it moults in 3 to 13 days to the first nymphal stage. The nymph is active, and comes out at night to feed upon an available host. If the nymph is destined to become a male adult, it moults three to five times; if it is a female it moults three to seven times. A single blood meal is taken between each moult and each stage requires 5 to 13 days. Should the nymph be unable to find a host it can survive starvation for more than a year. The adult males and females feed intermittently, but can resist starvation for 10 months or more. Fertilization takes place in the crevices about the floors and walls of the hut which serve as hiding places for the active stages. Following fertilization and feeding the female may start laying eggs after eight days. Eggs are laid in small batches at intervals of several days between the intermittent feedings. Adults may live for a year or more.

***Argas persicus*. The fowl tick.** In the southern United States it is known as the *chick tick*. It is found throughout the warmer parts of the world. Domestic fowls are its favorite hosts. The active stages hide in crevices in the hen house, and come out at night to feed. The larvae remain attached to the host for 3 to 10 days; then detach and seek a suitable shelter, where they moult to the first nymphal stage. There are three nymphal stages. The nymphs and adults feed rapidly, taking only small meals of blood. Adults may live for three years or more, and all stages can withstand starvation for months.

The hard ticks differ from the soft ticks not only in morphology but also in their life cycle. This cycle may be illustrated by that of the Rocky Mountain *tick*, *Dermacentor andersoni*. This species is found in the Rocky Mountain region of the United States and Canada. The natural habitat is the fields and woods in which the host animals live, and as the mountain range is subjected to severe winters the ticks hibernate as unengorged adults or nymphs in suitable shelters under

bushes, etc., on the ground. During the first warm days of spring the adults emerge from their hiding places and crawl onto bushes or other vegetation where they wait for a host to pass by. Hosts of the adults are larger mammals such as cattle, sheep, and man. When they brush through the vegetation in which the ticks are resting the latter attach themselves quickly. On the host, the adult male takes a number of small meals of blood; between feedings it seeks out the females which are attached by their mouth parts to the host. The male crawls beneath the attached female and effects coitus. A male will mate with several females. The males remain active for a long period of time, and it has been suggested that because they feed often, the males may be especially important in transmission of animal diseases such as anaplasmosis. The female and immature stages of hard ticks take only one meal of blood, so that disease organisms must survive from stage to stage and generation to generation in order to reach a new host; the males, on the other hand, may leave a dead animal, or be transferred from animal to animal upon bodily contact of the hosts, and thus become potentially a more effective mechanism for immediate transfer of pathogens.

The female, although attached to the host, does not begin to engorge until after she has been fertilized. Engorgement is completed in 9 to 10 days, and the greatly distended tick then drops to the ground, where she finds a crevice or some other suitable hiding place, and after a preoviposition period of a week to a month, eggs are laid over a period of about three weeks, in a single large batch numbering several thousand. The adults are active until midsummer. The eggs undergo an incubation period of about a month, so that the six-legged larvae appear in the early summer and are active until late summer. They attach themselves to various species of rodents and not to large mammals. They engorge in two to eight days; then drop off and find a hiding place on the ground. After a quiescent period of about three weeks the eight-legged nymph appears. By this time the season is well advanced. In the fall the nymphs emerge and attach themselves to small mammals such as ground squirrels and rabbits, but not to large animals. The nymphs engorge in 4 to 9 days, but if unable to find a host they may live for 10 months or more. The nymphs may be found, therefore, throughout the summer and it is possible for them to overwinter a second time. The engorged nymph goes through a quiescent period on the ground of three or four weeks, and then moults to the adult stage. These adults, emerging late in the summer, do not feed before going into hibernation. The total life cycle, therefore, requires two years for its completion. Adults which do not encounter a host will live for months, and so they, too, are able to overwinter at least twice. Some ticks, therefore, may require at least three years to complete their development.

Each stage of *D. andersoni* thus requires a separate host. Periods of attachment alternate with quiescent and host-seeking periods spent in the habitat. This is known as a three-host cycle. An important point in the relation of this cycle to the epidemiology of diseases is that the immature stages feed upon rodents and the adult stages attack large animals and man. Thus, rodent microparasites taken up by larvae and nymphs can be transmitted to man by the adults.

*Dermacentor variabilis* is the American dog tick. Its range includes most of North America except for the area inhabited by *D. andersoni*. Dogs are the preferred host of the adult ticks, but other large animals, as well as man, are also

y. The immature stages are found on wild mice and other rodents. The developmental cycle is much like that of *D. andersoni*, but there are variations in the life cycle depending upon latitude. In colder regions adults overwinter and are

Fig. 7-17. A Rocky Mountain spotted fever tick (*Dermacentor andersoni*). 1, adult female, unengorged, dorsal view; 2, adult male, dorsal view; 3, adult female, unengorged, ventral view; 4, adult male, ventral view; 5, adult female in act of depositing eggs.

in early summer, but larvae and nymphs may be found on their rodent hosts throughout the winter. The ticks may be encountered in wooded and grassy areas. Because of the preference for the dog as a host, they are more closely associated with the human environment than is the Rocky Mountain wood tick. *Haemaphysalis sanguineus*, the brown dog tick, is a common pest in houses and kennels. All stages attack dogs. In the Mediterranean region this species attacks

man as well as dogs, but in the Americas man seldom appears to be bitten. It has wide distribution in the tropics and subtropics, and its range seems to be expanding rapidly perhaps through movement of dogs. In the United States it was known a few years ago only from Brownsville, Texas, but now it is fairly generally distributed throughout the country.

*R. appendiculatus*, *R. sinus*, and *R. evertsi* are important pests of domestic animals in Africa.

*Haemaphysalis leporis-palustris* does not attack man, but appears to be of importance in that it may help maintain a reservoir of infection of diseases among rabbits. All stages attack rabbits, and the immature stages are found as well upon ground inhabiting birds. It is found throughout North America and has been reported from Mexico, Central and South America.

*Boophilus annulatus*, *decoloratus*, etc., attack cattle and as the larvae, nymphs and adults remain on the host continuously, these species are known as one-host ticks. They are vectors of piroplasmiasis. Through systematic dipping and quarantine *B. annulatus* has been exterminated from the United States, except possibly in a few small inaccessible pockets along the Gulf Coast.

Fig. 7-18. The Texas fever tick (*Boophilus annulatus*).

*Amblyomma americanum* attacks man and wild and domestic animals in North America and Mexico. It is said to be present in South America also.

*A. cajennense* is found in Mexico, Central and South America, and the West Indies; it is also reported from the tip of Florida and the vicinity of Brownsville, Texas. Wild and domestic animals serve as hosts, and all stages will attack man.

*A. maculatum* is of considerable economic importance in the southern United States. The adults attach to the ears of cattle and other animals, and the wounds made by them induce oviposition by the destructive primary screwworm fly. Immature stages of this tick feed upon small wild animals and birds.

*A. hebraeum* and *variegatum* are important parasites of domestic animals in Africa.

The genus *Ixodes* contains a number of species which are found upon wild and domestic animals. Some of them attack man as well. Important species are *I. holocyclus* in Australia, *I. ricinus* in Europe, *I. persulcatus* in Russia and Siberia, *I. scapularis* of southeastern United States and *I. pacificus* of the west coast of United States.

Aside from their role as disease vectors, ticks are important parasites because

the direct effects of their bites, which result in irritation and blood loss. Jellison and Kohls (1938) describe a tick-host anemia due perhaps to exsanguination of the host by large numbers of the parasites, although the authors suggest the possibility of the introduction by the tick of a substance affecting the hematopoietic system or which destroys the blood cells. Normal bites produce an edematous inflammatory lesion, but Trager (1939) has shown that an immunity can be acquired to ticks. Guinea pigs previously infested by larval *D. variabilis* respond to reinfestation with a leukocytic infiltration of the tissues in which the mouth parts of the ticks were inserted. The epithelium at the edges of the bite area becomes thickened and folds down beneath the mass of leukocytes. The tick thus becomes walled off from the source of blood and dies without becoming engorged.

Tick paralysis is caused by females of certain species of ticks. Males are seldom involved, presumably because they take only small meals of blood. The paralysis is presumed to be due to a toxin contained in the salivary secretion of the slowly engorging female. The offending tick is usually found attached to the head or in the vicinity of the spinal column; however, paralysis may also be caused by ticks attached to other parts of the body. It begins at the lower extremities and gradually ascends; if the tick is not discovered and removed death may ensue. Tick paralysis causes considerable loss among domestic animals. Man is also affected, and a number of cases have been reported in children. Cases in children are likely to be confused with poliomyelitis. Removal of the tick results in recovery. Ticks known to be capable of causing paralysis include *D. andersoni* and *variabilis* in North America, *Ixodes ricinus*, *Haemaphysalis cinnabarina*, and *Boophilus calcaratus* in Europe and the Mediterranean region; *I. pilosus*, *I. rubicaudus*, and *Rhipicephalus* in Africa, and *I. holocyclus* in Australia. Ransmeier (1949) has recently described several cases which he observed in children.

The control of ticks may be considered under the headings of protective measures and measures of attack. Persons entering tick-infested areas may protect themselves by wearing clothing through which ticks are unable to penetrate. This may include the use of boots into which the trousers are tucked. Following exposure the entire body should be examined for the presence of ticks. Although the mouth parts may be inserted into the flesh, actual engorgement proceeds slowly, and prompt inspection will prevent feeding or at least possible introduction of pathogens. Engorged ticks may be removed by a steady pull with the fingers or forceps. Care should be taken not to break off the mouth parts, and as infectious agents exist in the tissues, crushing of the tick must be avoided. The point of attachment may be treated with a solution of carbolic acid, silver nitrate, or iodine.

Various compounds have been tested as repellents, but none so far has been found to be completely satisfactory. Indalone, dimethyl phthalate, and benzyl acetate were found to give some measure of protection against immature stages. These materials were tested at the rate of 150 to 200 ml. per suit of clothing. They may be used as barriers by impregnation of a four- to six-inch wide strip of material along the margins and openings of the clothing, such as the sleeve openings and cuffs of trousers. Brennan (1948) reported excellent protection for 10 days against nymphs and adults of *A. americanum* through impregnation of clothing with an acetone solution of N-butylacetanilide. Each suit received two ounces of the solution. Garments may also be impregnated by dipping in a 5 per cent emulsion.

Cole and Smith (1949) also found it to be an effective repellent and safe for use on clothing at the rate of 2 gm. per square foot of cloth, but stress the fact that it is very toxic when applied directly to the skin. Since it should not come in contact with the skin, untreated underwear should be worn with impregnated clothing. Other materials are in the process of being tested but cannot be recommended until after their effectiveness and toxicology are better known.

Ticks may be attacked either in the environment or while they are attached to their animal hosts. Dogs may be treated with derris powder containing at least 2 per cent rotenone, or with a 10 per cent DDT dust. The derris appears to be more effective than DDT against the American dog tick. Bishopp and his associates recommend a dip made of two ounces of derris or cube powder, one ounce neutral soap, and one gallon of tepid water. After being applied thoroughly to the dog, it is allowed to dry on.

Large animals are treated with various tickicides in the form of dips, washes, sprays, and smears. Dips containing arsenic, rotenone, nicotine, coal-tar creosote, cresol, and sulphur have been widely used. Detailed instructions in their use is given in Bulletins No. 798 and 1057 of the U. S. Department of Agriculture. As a result of a great deal of experimentation in the use of DDT, benzene hexachloride, and related compounds, the U. S. Department of Agriculture at present recommends toxaphene or a mixture of DDT and lindane for treatment of domestic animals with sprays or washes. Sprays are prepared by diluting with water emulsion concentrates or wettable powders. The toxaphene spray should be diluted to 0.5 per cent and the DDT-lindane spray to contain 0.025 per cent lindane and 0.5 per cent DDT. They may be applied by means of power sprayers or hand sprayers to all parts of the animal and to the ears. These materials will eliminate the initial infestation and give protection against further attack for two or more weeks.

Premises such as poultry houses, dog kennels, dwellings, and caves may be treated with residual DDT or the other chlorinated compounds. The 10 per cent DDT dust may be used effectively in homes and kennels against the brown dog tick.

For area treatment, Gouck and Smith (1947) found that spraying of vegetation with emulsions at the rate of one to two and one-half pounds of DDT per acre gave varying results against *D. variabilis* but they consider that from two to three pounds of DDT per acre would bring about satisfactory control. One pound DDT per acre brought about effective control of *A. americanum* and *I. scapularis*.

**Parasitoidea.** This superfamily contains a large number of mites, some of which attack man and animals. Some of the latter are serious pests and also act as vectors of diseases.

*Liponyssus bacoti*, the tropical rat mite, has a wide distribution and appears to have been carried from the Mediterranean region by rats. The habitat of the mite is rat harborages; those situated in and about houses will permit the mite to transfer their attention from rats to man. The active nymph and the adults are parasitic and require blood for their development and for oviposition. On man, all parts of the body may be attacked, but there is a preference for the areas with the most tender skin. The victim may respond with a dermatitis consisting of pruritic, papular eruption; scratching may result in secondary infection. It has been thought that this mite is responsible for maintenance of murine typhus and

and its transmission to man, but it would appear that it is not a very efficient vector of either murine typhus or rickettsialpox. It is a natural transmitting host of the mite of cotton rats, *Litomosoides carinii*.

The adult female, *L. bacoti*, can become engorged in 10 minutes, but because feeding is interrupted frequently, she may remain on the host for as long as several days. She may wander from one host to another before completing feeding. Males, which take only small meals of blood, may also remain on the host for as long as two days. The female may live for two months or more, during which time she will engorge several times and lay several small batches of eggs. Fertilized females produce eggs parthenogenetically which give rise only to males; males are capable of fertilizing females. Eggs are laid in the nest or burrow of the host; they hatch into six-legged larvae which do not feed; the larva sheds its skin and so becomes the eight-legged protonymph which attaches to the host for a blood meal; it then transforms to the nonfeeding deutonymph, which eventually moults to the adult stage. The entire cycle may take as little as 13 days. Control of this mite is primarily one of rat control. DDT dust appears to have no effect upon it.

Other species of *Liponyssus* are parasites of birds. *Dermanyssus gallinae* is the common chicken mite. Although encephalitis viruses have been isolated from them, these mites are no longer thought to act as vectors or reservoirs for these viruses. *Dermanyssus sanguineus*, which parasitizes rats and mice, will also attack man, and this species has been shown to be a vector of rickettsialpox. *Echinolaelaps* and related species are common on rats; they do not attack man.

**Libyosomaidea.** Some species of these free-living mites are intermediate hosts of *Haemonchus contortus*, the tapeworm of sheep. Infection of the sheep occurs through the action of the mites living in the grass; the mites become infected by eating the faeces passed with the sheep's excreta. Certain other tapeworms of animals go through part of their developmental cycle in these mites.

**Personemidae.** To this superfamily belongs *Pediculoides ventricosus*, the grain mite. The female retains within her body the developing young until they reach maturity, and thus becomes greatly distended. The mites feed upon insects and grains, straw, and other plant materials. When handling such materials, or when sleeping upon straw-filled mattresses, the mites will attack man and cause dermatitis with vesicles and pustules which may be quite severe and cover the whole body. Pruritis is intense, and it may be accompanied by mild fever and albuminuria. The condition is remedied by further avoidance of straw or other sources of infestation.

**Tyroglyphidae (Tyroglyphoidea).** This superfamily contains a number of tiny mites which live in stored foods, grains, etc. People handling these materials are affected by a pruritic eruption known as "grocer's itch," "copra itch," etc. The lesions consist of small erythematous papules which develop on those parts of the body which come into contact with the material. Hase (1929) considers that the dermatitis due to the tyroglyphids and also to *P. ventricosus* is the result of allergy which develops through contact with the mites. The mites do not necessarily cause the dermatitis by their bites; rubbing of dust or infested materials containing the mites on the skin will produce the dermatitis very rapidly in sensitized persons.

There are many reports of tyroglyphid mites being found in the digestive and urinary tracts. In the intestine the mites appear to be able to live for a time, but it would seem rather doubtful that they could reproduce and set up a permanent infestation. Some patients, however, may be affected for months. It is possible that such persons are continually reinfesting themselves by ingestion of contaminated foods. As an example of how heavily infested foods may be, Hase estimated that in a feed box containing bran there were 3,000 *T. longior* per square centimeter of surface. He concludes that the severity of the intestinal symptoms depends upon the degree of sensitivity to the mites on the part of the patient. It has been suggested that the mites may gain entrance to the urogenital tract through use of unclean catheters and douche tips.

Inhalation of mite-laden dust may produce asthma and bronchitis, which is accompanied by a high eosinophilia. Carter and others (1944), who examined patients suffering from tropical eosinophilia, observed *Acaroid* and *Tarsonem* mites in the sputum and suggested that they could be the causative agents of this condition. Treatment with organic arsenicals appears to be effective.

**Demodicoidea.** *Demodex folliculorum* is a minute, elongate mite which lives in the hair follicles of man. It is thought by some that there is a high rate of infestation. Ordinarily the mites appear to cause no symptoms. Several species of *Demodex* infest animals; dogs suffer severely from demotectic mange.

**Sarcoptoidea.** This superfamily contains a number of parasites of birds and mammals, including *Sarcoptes scabiei*, which causes scabies in man. Animals have their own scab mites, and although animal breeders occasionally acquire mites from domestic animals, these infestations appear to be transitory. *Human scabies* are acquired through contact with other infested people, and the disease spreads through groups of people living in intimate contact. The disease is often a problem among military personnel, school children, and the like, but from Mellanby's (1941) observations it would seem that to acquire scabies far more intimate contact is necessary than that ordinarily occurring between soldiers, school children, or workers in industrial plants. In view of the widespread belief in the extreme contagiousness of the disease, it is well to review in some detail Mellanby's experiments. Mellanby found that blankets and underclothing were not a source of infestation a day or two after they had been used by scabies patients. In his experiments, volunteers who used a bed immediately after it had been vacated by a scabies patient failed to acquire the mites. In 32 experiments, volunteers did not acquire the mites from underclothing immediately after it was removed from scabies patients; only 1 of these men developed infestations. The mites were readily transferred from one person to another who slept together, and Mellanby concludes that scabies is normally transmitted by personal contact either of a slight or of a venereal nature. However, many people who have had experience with scabies will insist that intimate contact may indeed be slight for transmission to occur; Bhandari recently suggested that a dry, cracked skin is one condition which permits an infestation to take place readily.

The pregnant female mite burrows into the horny layer of the skin, and when scratched out, remains in her burrow for the rest of her life. Egg laying begins a few hours, and the eggs appear at the rate of two or three a day for about 2 months. Larvae hatch from the eggs in three or four days; they leave the burrow

enter the hair follicles. The larvae moult to the nymph stage; the nymphs also moult in the hair follicles. The nymph moults to become either an adult male or an immature female. The males make short burrows, but it is thought that they spend most of the time on the skin, in search of immature females. Mating probably takes place on the surface of the skin, and the pregnant female then enters her burrow. The entire life cycle requires 10 to 14 days. It is thought that transmission from one host to another is usually accomplished by the newly fertilized female.

Mellanby found that infestations occur most frequently on the hands and other sites are the elbows, feet, penis and scrotum, buttocks, axillae, and in women, the nipples. In very young children all parts of the body are attacked.

Neurotic scabies occurs when the patient becomes sensitized to the presence of the mites. This takes place about a month after the infestation has been acquired. At first there is severe itching sets in which may keep the patient awake at night; this, accompanied by a rash which occurs in patches, is highly suggestive of scabies. The diagnosis should be based upon the finding of the mites in the burrows. Once an infected burrow is found, the mite can be removed from the end of the burrow with the point of a needle. In sensitized patients vesicles form behind the burrows in the deeper layers of the epidermis, but according to Mellanby they also occur independent of the burrows. Follicular papules are thought to be due to the presence of the larvae and nymphs. Scratching permits bacterial invasion of the skin and may lead to pustules, boils, impetigo, or eczema. Norwegian or crusted scabies refers to severe infestation accompanied by thick crusts consisting of dried mites, dead epithelium, and dead mites. Mellanby suggests that this may develop in persons who have become immune and tolerate great numbers of the mites without responding by scratching.

Because the mites are unable to live for more than a short time away from the skin, the sterilization of bedding or other fomites would hardly appear to be necessary. Frequent laundry and cleaning will destroy the mites in the clothing. As the infestation is most likely to spread to all members of the family, treatment should be given to the entire family.

In treating scabies, a distinction must be made between the destruction of the mites in the skin and the curing of the secondary bacterial infections. Following the removal of the crusts through bathing and rubbing of the skin with a cloth, the scabicide may be applied, and then, if bacterial infection has occurred, the latter may be treated with calamine lotion, 2 per cent silver nitrate solution, or with other remedies recommended by dermatologists.

The destruction of the mites in the skin is not difficult, and may be accomplished without the preliminary bath. Sulphur has been a time-honored scabicide, and may be used effectively as an ointment containing 10 per cent sulphur. The ointment may be incorporated in a vanishing cream base. The disadvantages of sulphur ointment are its messiness and the possibility of dermatitis due to over-application.

More recently, benzyl benzoate has been shown to be an effective scabicide. A cream may be formulated of equal parts of soft soap, isopropyl alcohol, and benzyl benzoate (Obermayer, 1943). The following emulsion is easily made and according to Mellanby is practically painless even to babies:

Benzyl benzoate . . . . .	200 ml.
Stearic acid . . . . .	20 gm.
Triethanolamine . . . . .	5 or 6 gm.
Water . . . . .	enough to make 1,000 ml.

Melt the stearic acid with the benzyl benzoate in a water bath. Mix the triethanolamine with half the quantity of warm water and pour into the stearic acid-benzyl benzoate mixture cooled to about 30° C; shake to form an emulsion and add water to produce required volume.

Treatment with this emulsion may be preceded by a bath if facilities are available. After the patient is dried, the emulsion is applied to the entire body from the neck downwards; this may be done with a paint brush. The material is allowed to dry on the body. A single treatment will ordinarily eradicate the infestation but a second treatment on the following day or within a week may be advisable in some cases.

The NBIN concentrate, as noted above, is a combination treatment for scabies and lice. It is diluted with 5 parts of water and about 60 to 75 ml. are sprayed or sponged over the body. The patient should not bathe for 24 hours. A single treatment is usually sufficient, but occasionally a second treatment may be desirable after about a week.

Benzene hexachloride is toxic to *Sarcoptes*, and recently Edeson and Wharton reported that a 0.2 or 0.5 per cent solution of the gamma isomer of benzene hexachloride in cocoanut oil gave results that were as good as those obtained with the benzyl benzoate emulsion. The material was applied to all the body except the head with a paint brush. One should note that these tests were conducted upon experimental cases of scabies, and that neither the benzyl benzoate nor the benzene hexachloride solution was effective if applied only once.

A useful summary of the biology and control of scabies is given in a manual by Mellanby (1943).

**Trombidoidea.** These are the harvest mites; the larvae are called "*chiggers* or *red bugs*." The adults and nymphs are free living, and appear to feed primarily upon the eggs of insects which they find on the ground in the shelter of clumps of grass, vegetative debris, etc., which forms the habitat for the mites. The larvae are parasitic upon arthropods or vertebrates; among the latter are a number of species belonging to several genera which attack man. The latter, in addition to being severe pests, are vectors of *scrub typhus* or *tsutsugamushi disease*. The life cycle of the *Trombiculids* may be summarized as follows: the adult female, which may live for over a year, lays her eggs singly at the rate of 1 to 15 per day on the surface of the ground. They hatch into a quiescent deutonymph, from which the parasitic six-legged larva emerges. The larva attaches itself to an appropriate host and remains there several days, and when engorged, drops to the ground. It finds a suitable shelter and transforms to the quiescent nymphochrysalis stage. After several days an active nymph appears, which lives for two weeks to two months before it becomes quiescent and becomes the imago-chrysalis. The adult emerges in about a week.

In feeding, the larva grasps the skin of the host with the palpal claws, pierces the skin with the chelicerae, and then injects a salivary secretion which dissolves the tissues of the host. The host tissues react by forming a tube, called a "stylostome," and the mite sucks up the dissolved tissues through this tube.

chiggers are encountered in grassy areas or in the transitional zone between fields and woods, and in other situations which furnish shelter for the wild animal hosts. Amphibians, reptiles, birds, and rodents are important hosts for the chigger. The important pests of man in the Americas are *Trombicula batatas*, *T. lewisi*, *T. göldii*, and *T. alfreddugèsi*. *T. autumnalis* is the common species attacking man in Europe. In the Australasian region, the Orient, and India the two most important species on man are *T. akamushi* and *T. deliensis*; these are very closely related and may be varieties of a single species.

In former years, flowers of sulphur were used liberally in the clothing to protect against chigger bites, and on lawns, etc., to kill the mites in the grass. More effective chemicals were discovered during World War II.

Dimethyl phthalate, dibutyl phthalate, dimethyl carbate, indalone benzyl benzoate and Rutgers 612 will protect against chigger attack when used either alone or in combination, as in the 6-2-2 formula. Travis and his associates also recommend the following formulae as being effective against mites and a wide range of insects:

Dimethyl phthalate	. . . . .	1 part
Rutgers 612	. . . . .	1 part
Indalone	. . . . .	1 part
Dimethyl phthalate	. . . . .	3 parts
Indalone	. . . . .	1 part
Dimethyl carbate	. . . . .	1 part

Diphenyl carbonate and benzil are also effective against mites; these materials are solids, and must be used with a suitable solvent.

These materials act as miticides rather than as repellents when used against chiggers. Dibutyl phthalate is slower in its action, and so does not protect so completely as do the other materials.

Miticides are applied to the clothing rather than to the skin. The outer clothing—trousers and shirts or jackets—and socks may be impregnated with about two ounces of the above materials, or one-fifth ounce of toxicant per square foot. The clothing may be dipped into a solution of the toxicants in dry cleaning fluid; about one and one-half quarts containing the two ounces of miticide is required for an ordinary set of clothing. Travis and his associates state that benzyl benzoate, benzil, diphenyl carbonate are preferable for the impregnation of clothing, as they are long lasting. Benzyl benzoate-treated clothing is still effective after two home washings, while those impregnated with benzil and diphenyl carbonate will last at least five washings.

Clothing may also be impregnated by dipping in an emulsion of the miticides. Emulsions can be made with soap, but the most convenient way to do so is to make a concentrate by adding 10 parts of a commercial emulsifying agent to 90 parts of the toxicant. This is diluted at the rate of one-half pint of the concentrate per gallon of water. After wetting the clothing, they are wrung out lightly and dried before being used.

Clothing may be impregnated by being sprayed with the materials. For individual protection against chiggers, perhaps the most convenient method is to apply the liquid preparations to the clothing by hand. Particular attention should

be given to the openings of the clothing; a barrier of miticide about a half inch wide should be placed around the cuffs, waistband, and fly of the trousers, cuffs, collar, and fly of the shirt; and on the socks. The material may be rubbed in by hand, or applied directly from the bottle by drawing the mouth of the bottle along the margins of the openings of the clothing.

Area control of chiggers for a period of 30 days has been obtained by dusting or spraying breeding areas at the rate of 10 pounds of benzene hexachloride per acre.

**Order Araneida. The spiders.** The only spider whose bite may have serious consequences in man is the black widow spider, *Latrodectus*. *L. mactans* is widely spread in the United States, and may be recognized by the red or yellow hourglass-shaped marking on the underside of the abdomen of the female. The female's abdomen is about the size of an ordinary marble and, aside from the red or yellow markings, is jet black in color. The female spins her web in various sorts of protected sites, between rocks, in hollow trees, and the like, and the webs frequently are placed in dark corners of basements, outhouses, and beneath porches and seats. People are bitten when they disturb the arachnid. The bite may or may not be felt as a sharp prick. The poison, a neurotoxin, spreads rapidly throughout the body and within a few minutes or a few hours there may be dull aching muscular pains all over the body, or extremely severe pains accompanied by cramps and spasms in the larger muscles, causing the victim to writhe in agony. The abdomen becomes rigid and board-like, so that misdiagnoses of surgical abdomen are said to be common. There is difficulty in breathing, low fever, and brachycardia. Amnesia has been reported as a sequela. A number of deaths have been reported as having been due to the bite of the black widow. Although most healthy individuals would probably recover without treatment, the response to the bite is dependent upon the amount of poison injected as well as upon the physical condition of the victim. No case should be treated lightly. The treatment of choice appears to be the intramuscular or intravenous injection of 10 ml. of 10 per cent calcium gluconate solution, accompanied by hot baths or hot packs. Magnesium sulphate, 20 ml. of a 10 per cent solution, given intravenously, is another treatment that has had considerable use. Thorpe and Woodson (1945) discuss the problem of arachnidism in detail.

The large, vicious-looking, hairy tarantulas are said to be gentle creatures which seldom can be induced to bite, and when they do, the bite may be painful but produces only local effects.

**Scorpionida. The scorpions.** The appearance of these arachnids, with the powerful pincers and caudal sting, are familiar to all. They are nocturnal and hide by day beneath logs, rocks, etc., but may also get into houses. Most scorpions are relatively harmless; their stings may be painful but result only in a local reaction similar to that caused by the sting of a wasp, but in Mexico, North and South Africa, Asia, and India there are certain species which are able to cause death in man. Fatal cases occur principally in small children. The poison has been described as being a neurotoxin and hemolysin which produces muscular cramps, pyrexia, profuse perspiration, vomiting, hemorrhages of the stomach, intestine, and lungs, and increasingly severe convulsions. Basu (1939) reports that the cases he observed

ia manifested symptoms of allergy; death took place immediately, due to or in those who outlived shock, to edema of the lungs.

The most effective treatment is the use of anti-scorpion serum. Symptomatic treatment employed by Basu included hypodermic injections of morphia, application of hot packs or hot baths to the extremities, and administration of saline, glucamphor or ether and adrenaline. Stahnke (1950) found that the most successful treatment for the sting of the deadly *Centruroides* in Arizona was immediate application of a tourniquet and immersion of the affected hand or foot in ice bath for two hours. The tourniquet is removed five minutes after the hand or foot is placed in the ice bath. He recommends sedation only after convulsions have

## CONTROL OF RATS AND OTHER RODENTS

DAVID E. DAVIS, PH.D.

Rats and other rodents are the reservoir and source of several diseases of which plague is the most serious and widespread. A study, therefore, of habits and methods of suppression of rats, mice, and ground squirrels has become an important chapter in preventive medicine. In addition to their role in plague, rats are a source of leptospirosis, salmonellosis, murine typhus, and trichinosis as well as hosts of other parasites and infections which may be transmitted to man.

Rodents comprise more than one third of all living species of mammals and exceed any other mammalian order in the number of individuals. They have no canine teeth, but strongly developed incisors. Only the front of the incisors is covered with enamel, which keeps them sharp and chisel-like, owing to the more rapid wearing away of the softer dentine. The incisor teeth continue to grow throughout the life of the animal. The most extensive family of rodents is the Muridae which is divided into several subfamilies. Mice, *Mus*, and rats, *Rattus*, belong to the subfamily Murinae which is, therefore, the most important in preventive medicine. Mice can be distinguished from rats by their smaller size and the presence of a notch on the inner side of the upper incisors.

There are many different species of rats and mice, most of which remain indigenous and local; but there are three species that follow man to all parts of the world. These cosmopolitan murine rodents are the common house mouse, *Mus musculus*; the roof rat, *Rattus rattus*; and the Norway or brown rat, *Rattus norvegicus*.

**Description.** The different species of rats are identified by their color; length of ears, body, tail, and hind feet; shape of head; texture of pelage; number of mammae; and by the skull and teeth. *Rattus norvegicus* is easily differentiated from the *Rattus rattus* group by its larger size, more blunt muzzle, shorter ears which do not extend below the eyes when pulled downward, a thicker and shorter tail which is generally not as long as the body and has a less distinct ring-like appearance to the scaly covering, especially on the under surface. *Rattus norvegicus* females have 12 mammae, while *Rattus rattus* have but 10. There are other members of the genus *Rattus* with only 8.

The *Rattus rattus* group contains many subspecies and closely allied species, especially in the Malaysian region. For adequate identification, skins and skulls should be sent to a museum for comparison with named specimens. Three subspecies of roof rats (*R. r. rattus*, black; *R. r. alexandrinus*, brown with gray belly;

*R. r. frugivorus*, brown with white belly) have been introduced to many parts of the world and freely interbreed.

Albinism and melanism occur in all species; pied forms may occur. The white rat of the laboratory is an albino form of *Rattus norvegicus*.

**Distribution.** The genus *Rattus* contains more than 250 species and several hundred subspecies. The principal populations are in Asia and Malaysia. The Norway rats and roof rats have spread naturally throughout Europe and by means of man to practically every country and island in the world. The roof rats are generally limited to tropical and subtropical regions; or, when in northern regions, to the interior of buildings. Norway rats are distributed throughout the world but are found only locally in the Arctic and northern part of the temperate region. House mice also have a world-wide distribution. All three species have become feral in many parts of North and South America and live under wild conditions.

**Habits.** Roof rats, when present in conjunction with the more vicious and larger Norway rats, usually nest in the upper parts of buildings but in localities where members of the larger species are few or absent, roof rats will be found in large numbers in nesting places under buildings and in burrows or in the same harborage places generally preferred by Norway rats. In tropical climates, roof rats often nest in trees. Although Norway rats seem to prefer underground nesting places, their nests may frequently be found inside of buildings even in the upper parts of them when so constructed that they afford abundant rat harborage.

In mild climates, all of the cosmopolitan rodent species, even the house mouse will be found infesting the fields and brush considerable distances from buildings. Roof rats have a greater tendency to an exterior existence than the other species while Norway rats seem to have greater preference for the vicinity of buildings. Most species of rats live entirely outside of buildings.

Norway rats are not as agile as the other species and are less expert climbers. In the open, rats seem to have defective vision and by daylight move slowly and uncertainly; on the contrary, in contact with the wall, they run with great speed. This fact suggests that the vibrissae (whiskers) serve as feelers, and that the sense of touch in them is extremely delicate. Rats prefer narrow places and overhead pipes and beams as highways, and habitually follow the same course to such an extent that these highways or runs can be detected easily by the dark, greasy trail they make. The finding of runs is useful in locating rat hiding places and in discovering defects that allow passage to hiding and nesting places; and also as valuable guides for placing traps.

**Movements.** Extensive migrations of rats have been reported but their size has been exaggerated. The report (Pallas) that in the autumn of 1772 Norway rats arrived from the East at Astrakhan, southeastern Russia, in such great numbers and so suddenly that nothing could be done to oppose them has been discredited. It is claimed that in 1903 a multitude of migrating rats spread over several counties of western Illinois, traveling in great armies and causing heavy losses. Over 300 were killed in a month on one farm. Such migrations have not been observed to occur as the result of plague among rats.

Several movements of rats from houses and barns to the fields take place in the spring with the crops, and there is a return in the fall. This seasonal migration has been noticed in large cities.

The seasonal prevalence of plague is due in part to the seasonal movements of rats, but the large migrating movements have not been connected with the prevalence of the disease.

**HOME RANGE.** Rats, like other mammals, tend to remain within a limited area called a home range, for long periods of time. In Egypt, roof rats and another semisocial rodent were found rarely to leave the native houses (Petrie and Todd, 1911). Norway rats in the city of Baltimore rarely leave the block. By marking, tagging, and recapturing rats it was found that about 75 per cent of the recaptures were within 40 feet of the previous capture. Furthermore, on a farm, 90 per cent of the recaptures were within 40 feet (Davis and others, 1948). In Hawaii, Spencer and Davis (1950) found that three species of rats have limited movements. House mice live within an area of only 10 to 20 feet in diameter (Long and others, 1950). In general, it may be concluded that an individual rat will live for many months within a limited area unless there are radical changes in sanitary conditions. In urban residential areas the diameter of the home range will be about 100 to 150 feet.

When rats are introduced into an area, the probability of dying is very high (Davis, 1953), and no appreciable increase in population occurs in the area until reproduction has kept the area population at the saturation point. The work of Creel (1915) showed that rats liberated in a strange place will travel long distances in search of a new home. However, after a rat has found a suitable place, it will remain within a small area for many months or until there is a change in the environment.

**ON VESSELS.** A few years ago rats were present on all vessels and the three cosmopolitan species had been spread to all parts of the world by sea. Norway rats are much less commonly encountered on vessels than the other species; they never exceed over 1 per cent of rats killed by fumigation at United States quarantine stations. Rats have easy access to vessels as they lie at dock; many rats are probably stowed aboard in cargo.

At the present time, it is almost a universal procedure to include rat proofing as a standard requirement in contracts for new ships, both in American and in foreign shipyards. Many old vessels have also instituted measures that make them relatively rat proof. These procedures have markedly reduced the rat infestation on many ships and consequently lessened the dangers from rat-borne diseases.

It is important to prevent the introduction of rats on vessels at plague-infected ports; it is also important to prevent the passage of rats from ship to shore, particularly if the vessel is from a plague port. In extreme cases the ship should not approach the dock, but cargo should be handled during daylight by means of rat-proof lighters. Cargo which might harbor rats should be inspected, sometimes opened and repacked, or fumigated. Vessels from plague-infected ports found by inspection to be rat infested at time of arrival should be fumigated at once, whether empty or loaded, and rats that are killed by fumigation should be examined for evidence of plague. Cargo of such vessels should be inspected as discharged to determine that it is not harboring rats.

Measures that reduce the probability of rats entering and leaving vessels are: the use of rat guards on all lines connecting ship with shore and idle lighters; guarding gangways during the day and raising them or lighting and guarding

them at night; removing cargo slings and other gear connecting with shore and not in use; and fending vessels six feet from wharves. Periodic rat-infestation inspections of vessels, with fumigation only when found infested, is a measure being universally adopted to displace the old procedure of periodic fumigation on vessels that trade at clean ports.

**Food.** Rats are omnivorous but as a group grains are their food of choice. Rats prefer fruits. Rats are like man in that they learn to eat the foods of the locality in which they live and will often ignore foods selected by rats in other places. On the other hand, those of the same species and locality show great divergence in their choice of foods. Most rats will take fresh meat. Bacon mixed with grain is the best bait. In the tropics, fresh cocoanut is one of the most effective baits that can be used. Starved rats will eat anything but this fact cannot be relied upon to bring results when preparing rat baits.

**Economic Importance.** The destruction of food, crops, merchandise, and property by rats is so great that this alone would justify active measures of suppression even though they were not responsible for human disease. Rats destroy growing grain, vegetable and other crops; they invade stores, destroy flowers, laces, silks, carpets, and eat fruits, vegetables, meats, etc., in markets; they destroy by pollution ten times more than they eat; they gnaw lead pipes and floors of houses; they ruin artificial ponds and embankments by burrowing; they destroy eggs and young poultry; they damage foundations and piers; in short, they have become the worst mammalian pest among us. Rats actually destroy more eggs, chickens, and game than all the wild animals combined.

The number of rats in an area may vary greatly according to conditions. A farm may have several thousand. Davis (1950) estimated about one rat for every 10 people in New York City; Brown and others (1955) one for 8 people in Baltimore.

**Reproductive Rate.** The number of young produced depends upon the environmental conditions and the stage of growth of the population. The reproductive rate is partially dependent upon the level of the population in respect to the carrying capacity of the area to support rats. Rats reproduce at all seasons of the year although in many areas there is a maximum in both spring and fall. The percentage of adult females that are pregnant varies from 18 to 40, depending upon location, age of female, season, and population growth phase. The annual incidence of pregnancy (number of pregnancies per year) varies from four to eight, according to locality. For rat control purposes the incidence of lactation is a more useful rate since it indicates how many litters are about to be weaned. The meager data available indicate an annual incidence of two to four per year. The number of young weaned at each lactation is probably about seven in Norway rats, since there is a loss of about 30 per cent of the embryos at parturition and during lactation. As a generalization, it can be said that the average female Norway rat weans about 20 rats per year (seven weanlings  $\times$  three litters) (Davis, 1951).

**Mortality Rates.** The annual death rate in an average rat population is about three rats per rat in the population, and the annual probability of dying for an individual is about 0.95 (Davis, 1953). For very young rats (weanlings) the death rate is about nine and the probability of dying within one year is at least 0.99. Females probably live longer than do males. However, there may be great variation from place to place, or from year to year (Davis, 1951). The available

ence suggests that population changes depend more upon changes in death than upon changes in birth rates.

**Rat Populations.** Since the spread and transmission of disease and the control best depend upon the characteristics of a population, it is important to describe behavior of a group of rats in contrast to the habits of the individual. After a reduction in numbers, a population grows logistically (Emlen and others, 1948) until it becomes stationary at a level that is determined by the capacity of the area to support rats. Killing procedures (poisons, traps, cats, etc.) are rarely sufficiently effective to keep the population at a low level. Actually, these procedures as generally practiced merely make room for other rats to grow up. The limitation of the population comes about by means of competition among rats for the amount of food and harborage available. Fierce fighting permits a few rats to dominate the others. These high-ranking rats feed and reproduce approximately normally but inhibit the growth and reproduction of the inferior individuals. The population, therefore, becomes stationary at a level determined by the environment.

The history of the rat population of a block in Baltimore illustrates the characteristics mentioned above. The population estimates were made by the method

Fig. 8-1. History of rat population in Baltimore, 1943 to 1950.

Emlen and others (1949). All rat signs, such as holes, feces, tracks, etc., were recorded on a detailed scale map of the block. Then from these signs an estimate of the rats was made that was based upon a calibration from rat signs to rats trapped in a variety of places. The method has an error of about 10 per cent. In 1943, the block contained about 113 rats. An intensive experimental poisoning and gassing program by volunteers kept the population reduced for several years but could not be maintained because of the excessive cost. The population rapidly returned to about the same level as in 1943 and remained for four months

at that level. Two more poisoning campaigns temporarily reduced the population but it returned promptly to the level of 100 rats. Then, in early 1947, the population declined for no detectable reason and subsequently rose to a peak of 150 rats. This increase apparently was the result of an increase of the capacity of the block due to very poor sanitary conditions. The trapping of 74 rats temporarily reduced the population. In late 1948, sanitation and housing laws were enforced and the population has declined to only a few rats.

This history is an example of an accumulation of data (Davis, in preparation) that permit several conclusions: (1) even very intensive poisoning campaigns reduce the population only temporarily; (2) a population will increase to the capacity of the block to support rats and then remain at that level; (3) sanitation and rehabilitation will reduce the rat population drastically.

Fig. 8-2. Housing conditions before rehabilitation.

**Control.** The control of rodent population should be based on an alteration of the sanitary and other environmental conditions so that the rodents have neither food nor shelter. Competition among the individuals will reduce the population. In many cities striking reductions have resulted from sanitation and rat proofing and in some places without any killing procedures whatsoever (Davis, 1951). The fundamental points are: (1) it is administratively feasible to alter the environment enough to reduce the rats; (2) subsequent insanitary conditions develop slowly and can be checked by inspections; and (3) the results are improved living conditions for human beings and rat control. In contrast, killing procedures only reduce the population to a low level since the rats increase rapidly. Furthermore, the effort and money does not improve other living and sanitary conditions.

The details of control procedures are given in the publication of the U. S. Public

h Service entitled "Rat-borne Disease. Prevention and Control" published by Communicable Disease Center, Atlanta, Georgia. The following paragraphs summarize some of the important aspects.

**REHABILITATION.** Recently, rat control has developed into a phase of a better housing program, called rehabilitation. A procedure of inspection and law enforcement results in improvement of sanitation, plumbing, floors, cellars, and the buildings themselves. As an incidental but important part of this program the rats are eliminated. Rehabilitation is applied primarily to dwellings and has the same effect of improving housing conditions.

Fig. 8-3. Housing conditions after rehabilitation. Note removal of fences and trash.

**RAT PROOFING.** Rat proofing is applied primarily to commercial structures and is designed to prevent rats from doing economic damage. It is relatively permanent. However, rat-proof structures may become infested if the rats are allowed entrance, provided shelter, and provided food. Rats enter through drain pipes if left open; through doors, especially from alleys; and through basement windows. The lower parts of the outer doors of public structures, such as markets and wharves, should be tight fitting and reinforced with metal to keep the rats from gnawing through. Basement windows should be screened and doors provided with springs to keep them closed. The special points of ingress and egress of rats which must be guarded are hatches, ventilators, skylights, unused chimney flues, and openings around sewer, sewer, gas and steam pipes, and electric wires. Screens should be placed in tunnels and other strategic places to prevent rats wandering from one place to another in large groups of buildings and on ships.

Foundation walls should be laid without a break around the entire building and should extend not less than 18 inches beneath the surface of the surrounding ground, and should always be flush with the under surface of the floor above. Floor

joists should be imbedded in the wall or the spaces between the joists filled in and completely closed up to the floor level. Ground areas should be concreted with a layer at least three inches in thickness, finished with a wearing surface of cement about one-half inch thick. The walls of a wooden house should have one foot of concrete between the sheathing and lathing. All water and drain pipes should be surrounded by concrete where they pierce the walls. Rat holes may be closed with a mixture of cement, sand and broken glass, or sharp bits of crockery and stone.

Buildings may be raised 18 inches or more from the surface of the ground on piers, thus reducing rat haborage under them. Cribs for grain in the country may be raised and further protected with metal netting.

The chief refuges for rats in cities are provision houses, markets, warehouse slaughterhouses, restaurants, bakery shops, candy factories, and dwellings. In the country it is important to build corn cribs, barns, and granaries rat proofed with the wise use of cement, iron sheeting, or galvanized iron netting. The field rats of the tropics cannot be controlled by rat proofing for there is a continual abundance of exterior food.

**STARVING.** A scarcity of food is of utmost importance in assisting other suppressive measures. Garbage and offal must be disposed of so that rats cannot get at such stuff. Well-covered garbage cans should be required and the garbage frequently removed and burned. Slaughterhouses are centers of rat propagation. The offal is best disposed of by burning. Produce in provision stores may be protected by wire screens. Care should be taken also as to the disposal of remnants of lunches in office buildings and the disposal of organic waste generally.

**TRAPS.** Snap and cage traps are usually employed in most rat suppression campaigns. Snap traps are much cheaper, more easily handled, and possibly more efficient so that they have become the type most generally used. When placed in runs they may catch rats not concerned with their bait. When live rats are desired it is necessary to use cage traps. They should also be employed where there is danger of children, chickens, domestic animals, and wild birds being caught in the snap traps. The most efficient bait for any given locality is best determined by experimental trials. Bacon, fish heads, grains, fresh vegetables, fruits and, in the tropics, cocoanut are generally good baits. It requires ingenuity to trap rats.

**POISONS.** Killing procedures have in the past had great popularity because of their ease of application and their visible results. At the present time, poisoning is still widely practiced but with limited results except in some special areas. The use of poisons is worth while as a temporary measure in dumps, certain types of public housing, and for feral populations.

Some of the older poisons are still widely used. Red Squill is a favorite because its emetic action protects animals that can vomit. Strychnine, thallium, and arsenic are sometimes used but are somewhat dangerous. Barium carbonate and phosphorus are seldom used because of their erratic results.

In recent years, a number of new rodenticides have been developed. **ANTHRA** is specific for Norway rats but kills dogs and does not kill roof rats. Sodium fluoroacetate (1080) is a powerful poison for every animal and has been prohibited in many places because of human deaths. Warfarin (a derivative of dicumarol) is an anticoagulant that has a large safety factor because of the very low dose (0.1 per cent) that must be taken for four days to kill rats.

of these poisons require safety precautions and give only temporary results. It should also be mentioned that cultures of *Salmonella* (usually called rat viruses) had little effect on rat numbers and are obviously a hazard to public health.

**NATURAL ENEMIES.** The natural enemies of the rat are the larger hawks, owls, skunks, foxes, coyotes, weasels, mongooses, minks, dogs, cats, and ferrets. None of these animals is of value in rat eradication campaigns, although all of them help keep the rat population down to some extent. The mongoose (*Herpestes eremicus*) was introduced into the Hawaiian Islands from Jamaica in 1883 to destroy rats and is now present in great numbers. Although they no doubt have destroyed many rodents, the results have been far from satisfactory as they have had no general reduction in the number of rats but have destroyed many chickens and birds.

**FUMIGATION.** Rats may be killed with certainty in any inclosed structure by the use of sulphur dioxide, carbon disulphide, hydrocyanic acid gas, or carbon monoxide, provided all enclosed spaces are opened to allow penetration of the gas. Hydrocyanic acid gas is gradually displacing the use of sulphur dioxide in the fumigation of vessels. In the days before periodic fumigation was required and before the introduction of rat proofing, enormous numbers of rats were commonly found in the fumigation of ships. For instance, the S.S. Minnehaha, a vessel only 18 months in commission, fumigated in London in May, 1901, yielded a bag of 100 rats. Such an incidence could not occur with a modernly constructed rat-proof ship.

In conclusion, it is possible to control rats by removal of harborage and reduction of food supply. Adequate biological knowledge is available to permit intelligent planning of control measures, especially for Norway rats. Administrative details of problems differ from place to place and may require some effort for solution.

### DISEASES SPREAD LARGELY BY CONTACT WITH ANIMAL OR OTHER EXTRAHUMAN SOURCES

#### ANTHRAX

(*Splenic Fever; Charbon*)

Anthrax has figured prominently in the history of bacteriology and immunology. Anthrax was the first pathogenic bacillus to be seen under the microscope, by Pollender in 1849. Anthrax was the first communicable infection to be experimentally transferred, when Davaine and Rayer, in 1850, communicated splenic fever by the direct inoculation of blood containing these "infusoria" to susceptible animals. This established the etiological significance of the organism which they found in the blood of the sheep which they infected. Pasteur studied the disease and observed the multiplication of the bacilli under the microscope. He also grew the organism on coagulated blood derived from infected animals. Anthrax was the first bacterium to be grown in pure culture by Koch, in 1875. This was not only the first, but a convincing demonstration of the use of solid medium and the plate method for the isolation of pure cultures. Anthrax was the first dramatic demonstration by Pasteur, in 1881, of the prophylactic value of an attenuated virus. Pasteur's achievements in protecting sheep against anthrax closely followed similar laboratory experiments upon fowl cholera. The disease itself has long been known and has been recognized from early times. One of the best descriptions of an early epidemic of anthrax was by Athanasius Kircher, a Jesuit, who, in 1658, described an outbreak among cattle, occurring in 1617, which later spread to man, claiming about 600 victims.

Anthrax belongs to that group of infections which occur primarily in the lower animals and secondarily in man. The infection is found especially in cattle and horses, but also in sheep and other cloven-hoofed animals, and may be transmitted experimentally to mice, guinea pigs, rats and rabbits. Cold-blooded animals and birds, as well as dogs, are refractory. Zoologically, anthrax is one of the most widespread of infectious diseases. It is found in most parts of the world and in a large range of climates. In Siberia, where it has caused fearful destruction, it is still known as the Siberian "boil plague." Continental Europe has suffered much from its ravages, and it prevails in South America, Asia and Africa. In the U. S. it is a rare disease except in certain well-known infected areas where it exhibits permanent occurrence in animals. "Anthrax districts" have been recognized in southeastern South Dakota, northeastern Nebraska, part of the Texas Gulf Coast, and the lower Mississippi River Valley from Arkansas to and including the delta region (Stearns, 1942).

lateral outbreaks of animal anthrax in the Middle Western States during 1951-52 were traced to contaminated bone meal which had been imported.

**Human Anthrax.** In man the infection may enter the skin (*malignant pustule*) or the lungs (*wool-sorters' disease* or *rag-sorters' disease*) or may infect the digestive tract and produce intestinal lesions. The infection sometimes localizes in the brain and meninges.

In anthrax of the skin the infection usually enters through slight abrasions, scratches, or small wounds, especially on the forearm, hand, neck, or face. In hunters or persons who carry infected carcasses or hides, it is likely to occur on the neck and shoulders.

Many cases of anthrax in the United States and in England have been traced to shaving brushes made of horsehair. Vincent (1922) found anthrax spores in a shaving mug after the removal of the brush.

**Cutaneous Anthrax.** The cutaneous lesion (*malignant pustule*) has a characteristic evolution and appearance. It begins as a small, red, indurated area, in the center of which a vesicle develops. As it increases in size, satellite vesicles appear. The surrounding tissues become edematous. The center of the lesion softens and becomes necrotic and a characteristic dark brown eschar is formed. The lesion is painful. The regional lymph glands become swollen and tender. Malaise, fever, and general prostration develop in varying degrees. Regression may begin at any time. In 5 to 10 per cent of cases there is a progressive cellulitis, sepsis and shock.

*Wool-sorters' disease*, or anthrax of the lungs, appears to be due to the inhalation of anthrax spores. It is observed only among persons who handle skins or who work with horsehair, wool, or other raw materials from animals afflicted with anthrax. The symptoms are like those of pneumonia; this form is frequently fatal. Although the usual heat of cooking does not necessarily kill spores, in the United States there is no report of the transmission of anthrax to man by meat or milk. Intestinal anthrax is rare, but when it does occur it is rapidly fatal. The anthrax spore is exceedingly resistant to heat and external influences such as drying and sunlight, and also to germicidal agents.

**Prevalence.** In the United States human anthrax is mostly an industrial disease contracted through the handling of skins, hair or the animals themselves. Those especially exposed to the hazard are laboratory workers, veterinarians, meat inspectors, farmers, cattlemen and butchers, but especially workers with hides, hair, wool, etc. Of about 1,000 men exposed to the danger in Pennsylvania tanneries, 123 in all contracted anthrax in the course of 12 years, or more than 11 per cent of the number of directly exposed tanners. Seventy-three of these cases were due to the handling of cattle hides and 50 to the handling of goat hides. One fifth of the cases died (Smyth and Bricker, 1922). A special inquiry (Smyth and Higgins, 1945) revealed the occurrence of 408 human cases of anthrax in the five-year period 1939 to 1943. Information regarding the probable source of infection was obtained on all but eleven. In 20 per cent it was classified as due to handling of hides and skins, in 60 per cent to contact with wool or hair, in 16 per cent to direct contact with infected animals or soil (agricultural), and in the remaining 4 per cent to other miscellaneous sources. From 1945 to 1951 from 40 to 60 human cases were reported each year.

The causative organism is recovered and identified by inoculation of mice with material from the lesion, blood, tissues, or articles suspected of being contaminated; this technic screens out nonpathogenic contaminants.

An immune serum, made by inoculating horses with virulent anthrax bacilli, has been used in treatment. It is injected locally as well as intravenously. More recently, treatment with penicillin seems to be quite effective (Ellingson and others, 1946) and would seem to be the method of choice for many reasons.

**Control in Animals.** The prevention of the disease in man must first be directed to a suppression of the infection in animals by veterinary measures of control. Sick animals should be isolated, or, better, killed, and the carcasses burned or buried with lime at least six feet deep. The cadavers may be "tanked," that is, subjected to a prolonged exposure to steam under pressure. Tanks for this purpose are found in all the larger slaughter houses. It is important in handling the body of an animal dead of anthrax not to open it or shed blood, for the bacillus does not produce its spore except in the presence of oxygen; that is, the bacilli in the blood and internal organs will not sporulate as long as access to the air is prevented.

The neglect of precautions in disposing of anthrax carcasses favors the spread of the infection through the activity of carrion feeders. Buzzards may carry infection for long distances and contaminate clean ground or water through contamination on their feet and beaks. Dogs discharge anthrax spores in their feces 114 hours after feeding upon an anthrax carcass.

Anthrax spores may live months, even years, in the soil. Hastings (1923) found anthrax spores in a pond in a pasture in which the disease had occurred eight and one-half years before.

When an outbreak of anthrax occurs in a dairy herd, the herd should be quarantined under supervision of the state livestock sanitary authority until 10 days after the appearance of the last case. The milk during this period should not be used. Recommended procedures for control of anthrax in a dairy herd have been formulated in detail by the U. S. Public Health Service (Steele and Helvering, 1953).

**Vaccination of Animals.** That animals could be immunized against anthrax was demonstrated by the world renowned experiment which Pasteur conducted at Pouilly-le-Fort in 1881. With his associates, Roux and Chamberland, he found that when a virulent strain of anthrax was grown in broth at a temperature of 42° C to 43° C it was progressively decreased in virulence. For immunization purposes he prepared two types of vaccine. He injected first, fresh bouillon culture of a strain so attenuated that it was fatal for mice only and not for guinea pigs or rabbits (Pasteur No. 1). Twelve days later, he injected a less attenuated strain (which would kill mice and guinea pigs but not rabbits) (Pasteur No. 2). This method was subsequently used on a large scale and was a tremendous factor in the control of anthrax in animal herds. It was used on cattle, horses, mules, sheep, and goats. In practical use, however, it was not altogether satisfactory. A small percentage of the animals succumbed as a result of the vaccination. It required handling the animals twice. As the anthrax vaccine was actually a bouillon culture of the organism, it tended to become inert through autolysis if kept for any period of time. As these shortcomings became apparent, efforts to improve the method of vaccination were made and have continued up to the present time. In 1902, Sol

recommended a modification in which anti-anthrax serum was injected subcutaneously on one side of the body followed immediately by injection on the other side of a single dose of Pasteur's No. 2 anthrax vaccine. This method was later modified by Eichhorn (1925) in that a spore vaccine of the virulence of Pasteur's No. 2 strain was used in combination with a potent anti-anthrax serum. There are now a number of different types of vaccine commercially available. These include the spore vaccines given with or without simultaneous injection of serum, the vaccine injected intracutaneously, spore vaccine suspended in saponin, and the killed products (bacterins). Gochenour and others (1935) tested the effectiveness of a number of these products on sheep. In brief, it was found that all the types of the last mentioned type confer a considerable degree of immunity without causing any animal losses. None, however, affords complete protection in all the animals vaccinated.

While veterinary measures are effective in suppressing outbreaks of anthrax among animal stocks, there is no way of permanently eradicating the organism from the soil and vegetative cover of an infected area. Nor can the introduction of infection into new areas by the movement of livestock and the shipment of animal products such as hides, wool and hair be entirely prevented. Efforts to prevent the exposure of human beings to infection by regulations requiring an embargo upon importation of hair and bristles from suspected areas, and areas in which information is lacking, have not proved to be satisfactory. Enforcement is difficult or impossible. The prevention of human infections must be based on the concept that there is a potential hazard to persons employed in occupations which bring them into contact with animals or animal products. This hazard should be minimized so far as practicable.

The sale of hides from animals known to be infected with anthrax should be prohibited unless they have been subjected to a satisfactory disinfection process. Disinfection of hair and bristles from sources known or suspected of being contaminated should be obligatory before they are used or sorted. Employees in tanneries, woolen mills and factories utilizing animal hair in bristles should be under medical supervision. Efforts should be made to reduce skin injuries by the use of mechanical aids in handling heavy items and by wearing gloves when handling hides. Emphasis should be placed upon prompt surgical treatment of all skin lesions and medical examination of all suspicious lesions. Proper ventilation should be provided to carry off the dust where hair and wool are handled, especially about carding machines. Trade wastes and effluents from such plants should be properly treated before being discharged into streams and rivers to avoid contamination of overflow land used for pasturage. Since no satisfactory nonliving vaccine is available, immunization of human beings is impractical. The low incidence of the disease among those exposed by occupation does not justify specific prophylactic measures.

**Disinfection.** Disinfection for anthrax is difficult on account of the extraordinary resistance of the anthrax spores. It is further complicated by the fact that dependable methods are apt to injure the hides.

Steam disinfection is practicable for hair, but not for wool or hides. The wool and hides are seriously damaged by the action of the steam. Wool may be disinfected by formaldehyde used as given below. The method preferred for hides

is the hydrochloric acid-salt bath of Schattenfroh. Manufacturers object to the disinfection of hides with bichloride of mercury and formic acid, according to the Seymour-Jones method, on account of the apparent injury caused by such treatment.

**HAIR FOR SHAVING BRUSHES.** The disinfection of the hair used for shaving and lather brushes is accomplished by one of the following methods: (a) by boiling the hair or bristles for not less than three hours; (b) by exposing the hair or bristles to steam under not less than 15 pounds' gauge pressure for not less than 30 minutes with a preliminary vacuum of not less than 10 inches before turning on the steam (Schneiter and Kolb, 1948); (c) by exposure to streaming steam for not less than six hours; (d) by dry heat, 200° F, for 24 hours.

**SHAVING BRUSHES.** Any brushes found in the market which do not bear the name or the trademark of the manufacturer should be regarded with suspicion and should be returned to the source from which they were secured, or should be disinfected. Shaving brushes will stand boiling or steaming. The following procedure is believed to be effective:

The brush should be soaked for four hours in a 10 per cent formaldehyde solution. The solution should be kept at a temperature of 110° F, and the brush agitated as to bring the solution into contact with all hair or bristles.

**WOOL.** The following method is recommended for the disinfection of wool, goat hair and camel hair. A preliminary agitation with an alkaline solution of soda in water at a temperature of 102° to 110° F; exposure for 20 minutes in a 2 to 2.5 per cent solution of formaldehyde in water at a temperature of 102° to 105° F. The hair is then dried in a current of air at 160° F, and allowed to stand a short time in order that the formaldehyde may complete its germicidal action.

**HIDES AND SKINS. The Seymour-Jones Method.** To one pound of perchloride of mercury add 500 gallons of water, and to this mixture add five gallons of formic acid (commercial 50 per cent strength). In this bath steep the material for 24 hours.

**The Schattenfroh Method.** In a 2 per cent hydrochloric acid solution to which 10 per cent of common salt has been added steep the material for 40 hours at a temperature of 60° to 70° C. A quicker method can be used by substituting a 1 per cent solution of hydrochloric acid and 8 per cent of salt, provided the temperature of the solution is maintained at 40° C (104° F) for a period of six hours.

## BRUCELLOSIS

(*Undulant Fever, Malta Fever, Mediterranean Fever*)\*

Under a multitude of names, the human disease now generally known as *undulant fever* was differentiated during the latter part of the nineteenth century. The British Army Surgeon, Sir David Bruce, conducting studies on the Island of Malta in 1866-87, briefly described a "disease of long duration characterized clinically by continued fever, profuse perspiration, constipation, frequent collapses, rheumatic neuralgic pains, swelling of joints or orchitis." He isolated and identified the causative agent, which Hughes erroneously named several years later *Micrococcus melitensis*. Subsequent investigators, recognizing that the organism was not a bacillus but a pleomorphic bacillus, called it *Brucella melitensis*. The disease may be mistaken for typhoid fever, rheumatic fever or tularemia. Undulant fever is remarkable for its low mortality, recurrent attacks and long drawn out duration. The period of incubation is about two weeks but varies from one week to three weeks or possibly longer. A large proportion of infections is inapparent.

**Relationship between Undulant Fever and Contagious Abortion.** About 10 years after the British army surgeon Bruce disclosed the *Micrococcus melitensis* as the cause of Malta fever, Bang, a Danish veterinarian, discovered the cause of contagious abortion in cattle, which he called *Bacillus abortus*.

Two more unrelated diseases can hardly be imagined, yet Alice Evans (1918) discovered by ordinary laboratory methods that the Bang bacillus and the Bruce micro-organisms are indistinguishable. The observations of Evans were soon confirmed by her and Shaw (1920) and a number of investigators in other countries. Upon further study, Evans herself and others soon revealed a family group of closely related micro-organisms distinguishable from each other partly by their source and partly by absorption agglutination tests. This group is now called *Brucella* as a permanent memorial to the genius of its original discoverer.

**Brucella.** There are three species of *Brucella*: (1) caprine (*Sp. Br. melitensis*) causes the disease in goats; (2) porcine (*Sp. Br. suis*) causes the disease in hogs; (3) bovine (*Sp. Br. abortus*) causes the disease in cattle.

All three species may infect susceptible domestic animals or man. The caprine strain was the original organism of Bruce. It prevails widely among goats and is readily transmitted to man either through drinking goat's milk or handling the animals. It is the most pathogenic strain for man so far disclosed. The porcine strain causes abortion in hogs but is less serious for man. The bovine strain is the common cause of contagious abortion (Bang's disease) of cattle. Man seems to have a high degree of resistance to the abortus strain. During recent years, however, numerous cases of the human infection with this species have been recognized. Any one of the three types may infect goats, hogs or cattle and other species of domestic animals, particularly sheep, horses and dogs.

\* The disease is also known as febris undulans, febris sudoralis, Gibraltar, Neapolitan, Cretan, Cyprus or Danube fevers, abortus fever, melitensis septicemia, fièvre caprine, melitensis or Mediterranean phthisis, Munhinyo, goat fever, mountain fever, slow fever, Rio Grande fever, Bruce's septicemia, rock fever and Maltese fever. In 1913 the International Congress of Medicine agreed that the term *undulant fever* was the most satisfactory. Others prefer *brucellosis* for both man and animals.

**CHARACTERISTICS.** *Brucella* are small Gram-negative, coccobacilli occurring singly or in pairs, sometimes in short chains. The first generation of colonies in blood or urine develops slowly on artificial culture media. Minute dewdrop colonies appear after about four days of incubation, but cultures should not be discarded as negative until they have been incubated and observed frequently for two to three weeks. After having become established on ordinary media, they may be kept indefinitely by transplanting every six or eight weeks. *Melitensis* or *suis* strains grow well under ordinary atmospheric conditions, but for the *abortus* variety an atmosphere containing about 10 per cent of  $\text{CO}_2$  by volume is helpful if not essential for development. The three species are differentiated culturally by the bacteriological action of certain dyes by  $\text{H}_2\text{S}$  production and by glucose utilization. All three species are agglutinated by an antiserum prepared from any one of the three. Freshly isolated (S) strains of *Br. melitensis* can be distinguished from *Br. abortus* or *Br. suis* by careful agglutinin absorption technic.

**Laboratory Diagnosis.** There are five tests which are in general use: (1) cultivation and isolation of the organism from the blood, bone marrow, lymph nodes, joint effusions, urine, feces, exudates; (2) animal inoculation of suspected infectious material; (3) tests for allergy; (4) tests for serum agglutinins; (5) the opsonocytophagic test. The isolation of a pure culture of *Brucella sp.* from blood or tissues of patients or inoculated animals is the only means of proving the diagnosis. The reagents used in the intradermal test for allergy are suspensions of heat-killed *Br. abortus*, filtrates of old broth cultures ("melitin" or "abortin") and a nuclease protein extract ("brucellergin"). The interpretation of the test depends primarily upon the standardization of the material used. It should be employed in a dilution which will reveal specific sensitiveness with a minimum of nonspecific reactions. In a patient who is sensitive, both the local and the constitutional reaction may be severe. Read 48 hours after injection, with proper controls, a positive test is indicative of current or past experiences with *Brucella* organisms. An immune state may exist in the absence of skin allergy. This test is of questionable reliability in the diagnosis of chronic brucellosis. High agglutinating power sometimes develops in the blood of persons suffering from undulant fever. Titers of 1:5,000 are not uncommon. A titer of 1:80 or more is generally regarded as positive. On the other hand, the agglutinating power may be so low as to be misleading. The prozone phenomenon may constitute a source of error. A negative agglutination reaction does not exclude the diagnosis of undulant fever. Nor does a positive reaction necessarily indicate that the patient is suffering from brucellosis.

The opsonocytophagic test has been subjected to extensive evaluation; opinions vary as to its usefulness. It is unsuitable for routine diagnosis (Spink and others, 1952).

**RESISTANCE.** The *Brucella* genus is readily killed by heat. It succumbs in one hour at  $55^\circ\text{C}$ ; the majority die in 10 to 15 minutes at  $58^\circ\text{C}$ ; at  $60^\circ\text{C}$  all are killed. The thermal death point in milk is of practical importance. Temperature pasteurization ( $62^\circ$  to  $63^\circ\text{C}$ ) kill *Brucella* in three minutes. Phenol 1 per cent destroys the organism in 15 minutes. *Brucella* show remarkable resistance to dryness, and may remain alive for a month in dust. In damp manure they may survive 20 days.

**GOAT'S MILK AND MALTA FEVER.** We are indebted to the six reports of the British Commission for the Investigation of Mediterranean Fever (1905-07) for

undulant fever in Malta is spread chiefly through goat's milk. Before the  
es of this commission the common mode of infection was not definitely

usual source of milk in Malta was the goat. The udders, which are abnor-  
ng, often touch the ground and are liable to be soiled. It was first shown  
mit in the report of 1905 that goats could be infected by feeding them with  
*Brucella melitensis*. In the same year, Major Horrocks discovered *Brucella melitensis*  
milk of an apparently healthy goat. Further studies showed that one or more  
goats in every herd were excreting *Brucella melitensis* in their milk and  
nd that about 50 per cent of the goats reacted positively when examined by  
agglutination tests. All the available evidence points to their food as the main  
of infection in goats. The young goats, of course, are infected through their  
s milk. Horrocks and Kennedy considered that 10 per cent of the goats  
ng milk to various parts of Malta excreted *Brucella melitensis* in their milk.  
cretion of the specific micro-organisms may continue steadily for three months  
t any change occurring in the physical character or chemical composition of  
k and without the animal exhibiting any signs of ill health. On the other hand,  
cretion of *Brucella melitensis* in the milk may be intermittent, appearing for  
days and then disappearing for a week or more.

Major Horrocks in Report Number 5 of the British Commission shows a direct  
nship between the number of goats in Gibraltar and the number of cases of  
ant fever in man. With the reduction in the number of goats there was also a  
se in the number of cases of undulant fever, so that finally when the number  
ts had decreased to about 200, in 1905, the disease had practically disap-  
1.

he story of the steamship *Joshua Nicholson* is instructive. Sixty-one milch  
all healthy in appearance and good milkers (many being prize animals), and  
billygoats were shipped on board the cargo steamer *Joshua Nicholson* August  
1905, at Malta for passage to the United States via Antwerp. Many of the ship's  
any partook freely of the milk. The officers drank "mixed" milk collected in  
e vessel; the members of the crew each obtained the "whole" milk from one  
n his own separate pannikin. Subsequent bacteriological examination resulted  
e recovery of *Brucella melitensis* from the milk of several of the goats. Of 23  
on board who drank the milk on one or more occasions, no evidence whatever  
ailable as to 13; while of the remaining 10, nine suffered from febrile attacks,  
of them yielding conclusive evidence of infection with *Brucella melitensis*.

There is experimental evidence to show that monkeys can be infected by dry  
artificially contaminated with cultures of *Brucella melitensis*. The path of en-  
e may be through the nares, throat, respiratory passages, or alimentary canal.  
dust contaminated with the urine of cases of Malta fever has given rise to in-  
on in goats but not in monkeys. The experience gained during the work per-  
ed in Malta during 1904 and 1905 has convinced Horrocks that men are more  
eptible than monkeys and goats. Shaw's work on ambulatory cases among  
tese has also shown that opportunities for the infection of dust were plentiful  
Malta. Infected dry dust as a mode of transmission cannot, therefore, be discarded.  
There has long been a suspicion that undulant fever may be conveyed through  
bite of an ectoparasite; in fact, Captain Kennedy was able experimentally to

infect a monkey as a result of bites of mosquitoes (*Culex pipiens*) which had bitten patients suffering from Malta fever. This probably was an instance of mechanical transference of the infection, corresponding in all respects to a laboratory inoculation with fresh virulent material from a hypodermic syringe. This cannot be a frequent way by which the infection is transmitted in nature, for the specific organisms are found in small numbers in the peripheral blood of Malta fever patients. The British Commission found *Brucella melitensis* only four times from a total of 100 mosquitoes studied.

**Prevalence of Undulant Fever.** Recognition of brucellosis as a public health problem in the United States began with the finding by Craig (1905) of a case of undulant fever in a nurse who had never been out of the country. Gentry and Fenbaugh (1911) discovered a focus of cases in the goat raising section of Texas, along the Rio Grande River. An epidemic in Phoenix, Arizona, in 1922 was found by Watkins and Lake to be due to drinking unboiled goat's milk. Reports of cases giving a history of drinking unboiled goat's milk or being associated with the goat raising industry began to accumulate.

With the establishment of the true relationship of the *Micrococcus melitensis* of Bruce, and the *Bacillus abortus* of Bang, the origin of human cases from direct or indirect contact with cattle or hogs infected with contagious abortion was suspected and soon found. Keefer (1924), reported a case originating in Baltimore, Maryland, in which goat's milk could be entirely excluded as a cause.

By 1929, undulant fever had been recognized in every state of the United States. As differential diagnosis was better understood by physicians, the number of reported cases increased. During the four-year period 1942 to 1946, the median number reported annually for the country as a whole was 4,286. Incidence varied widely in different states, depending upon the state of development of the livestock industry and the spread of contagious abortion through herds of cattle, sheep, and hogs.

Similarly, in other countries as attention was directed toward the disease, undulant fever was found to be more common and widely distributed than had been suspected. It has become apparent that it may occur wherever goats, cattle, hogs, and sheep are domesticated. Areas in which it is known to be endemic are scattered throughout Canada, Mexico, the West Indies, portions of South America, Europe, Arabia, India, China, the Philippine Islands, and South Africa.

**Brucellosis in Cattle and Swine.** Approximately 5 per cent of the adult female cattle in the United States are infected with brucellosis. These infected cattle are confined to about 20 per cent of the herds throughout the country. It is estimated that the total annual loss from decreased milk production, fewer veal calves, and necessary replacement of dairy cows was approximately \$92,000,000 in the year 1947 (Spink and others, 1949).

When an infected animal is introduced into a susceptible herd an explosive epidemic may occur or the infection may spread insidiously from animal to animal over many months. Calves, up to the age of three and possibly six months, are relatively resistant to infection. During the first pregnancy is probably the period of greatest susceptibility. Not all infected animals abort. The spread of brucellosis to other animals is effected most commonly at the time of parturition or abortion and for two or three weeks following. The fetal membranes, chorion, fetus, and uterine discharges all contain brucella. There is a secondary localization of the organisms

teal ducts of the udder. Consequently, they are excreted in the milk of the cow. When the infection becomes established in the udder, it may persist for periods varying from a few weeks up to six or seven years or longer. Diagnosis is determined by a standard serum agglutination test. All animals showing a positive test are regarded as potential spreaders or carriers.

Brucellosis in swine occurs in various parts of this country but is not so widely distributed as in cattle. From packing house surveys it is estimated that the infection is present between 1 and 3 per cent. *Br. abortus*, the bovine type, has little or no virulence for swine and *Br. suis* is transmitted almost exclusively from pig to pig. In herds, the infection causes severe losses from abortion. For the most part it is a limiting disease. Many swine found infected by application of the serum agglutination test become negative within 90 days.

Although *Brucella* infections occasionally occur in other domestic animals (horses, dogs) they are relatively unimportant in the epidemiology of the disease in the United States.

**Modes of Transmission.** The two principal modes of transmission are by ingestion of raw milk or dairy products from diseased goats or cows, and by direct contact with infected animals in handling infected meat.

While the risk of contracting undulant fever from drinking goat's milk containing *Br. melitensis* is relatively great, a very low rate of human infection is usually found among the consumers of raw milk containing *Br. abortus*. Thus, Orr and Huddleson (1930) found in Michigan that in a group of 500 individuals equally divided into males and females of all ages, constantly exposed to the abortus organism through infected milk supply, only 1.4 per cent gave evidence of infection, and only 0.8 per cent showed any signs of active infection. The organism tends to concentrate in the cream layer. *Brucella* may survive as long as 25 days in butter and around two months in Roquefort cheese.

The frequency with which the disease is contracted by direct contact is reflected in the occupational selection for farmers, veterinarians, and workers in slaughterhouses, packing houses and butcher shops. Farmers and veterinarians are exposed to infection through contact with hogs and cattle in vaccinating, castrating, medicating, struggling animals, in the manual removal of placentas, and related procedures. On the basis of an epidemiological study of 354 cases of undulant fever in Iowa, Hensley and others (1930) estimated that approximately one-half were due to contact with infected animals, their tissues or discharges, the infection in all probability entering through cuts and small unnoticed abrasions of the skin. Of 420 strains of *Brucella* isolated from human cases and studied by Borts in the Iowa State Hygienic Laboratory, 62 per cent were *Br. suis*, 27 per cent *Br. abortus*, 12 per cent *Br. melitensis*. In a study of 268 cases in Minnesota, Magoffin and others (1949) concluded that approximately three fourths of all cases had had direct contact with infected animal material, but about one fourth of the patients presented no history of animal contact and had ingested raw milk. *Br. abortus* was isolated by blood culture from 86 per cent of these patients, *Br. melitensis* 8 per cent and *Br. suis* from 6 per cent.

Obviously, the epidemiological pattern with regard to age, sex, race, occupational selection, seasonal incidence, relative frequency of bovine, porcine and caprine strains, and other features will vary in different localities of this and other countries,

depending upon the character of the local animal husbandry, habits with regard to ingestion of raw milk and dairy products, and related factors.

Patients may excrete the organisms in the urine during the acute illness and sometimes during and after convalescence. Nevertheless, contact transmission from man to man is extremely rare. Where suspected, careful inquiry almost invariably reveals other more probable routes.

There are few diseases transmitted to laboratory workers so readily as undulant fever; in fact, most investigators contract it and are unable to trace their infection to any definite accident.

**Treatment.** The tetracycline antibiotics, especially aureomycin, usually induce subsidence of fever and other symptoms in several days, but the relapse rate is high. Administration of the drug should be continued for at least three weeks.

**Prevention.** The prevention of undulant fever due to the ingestion of milk or dairy products, whether from cows or goats, is a relatively simple matter. All milk, cream, cheese, butter, and ice cream should be properly pasteurized. Where pasteurization is not practicable milk should be boiled before use.

The prevention of undulant fever due to contact with animals or animal products is a much more difficult matter. Where brucellosis prevails among animal stocks, exposure of herdsmen, farmers, veterinarians, slaughter house employees, and butchers is inevitable. The hazard can be reduced somewhat by education. A safe and effective measure of artificial immunization with a vaccine suitable for human use has not been developed. Prophylaxis that would be fundamental and enduring consists in the elimination of brucellosis from domestic herds (Fleming and Roepke, 1949).

Experience of the past 50 years justifies the statement that brucellosis can be eradicated from any herd when the procedures best adapted to the particular herd are followed through under the direction of persons trained in the control of livestock diseases, provided the owner or caretaker of the animal gives his full cooperation. The recommendations of the Committee on Brucellosis of the U. S. Livestock Sanitary Association, the so-called National Plan, should be followed (Spink and others, 1949). These recommendations provide four different methods of procedure for the eradication of brucellosis from a herd of cattle. Principal dependence is placed upon two procedures: (1) the testing of animals for brucella agglutinins and elimination of reactors by slaughter, and (2) vaccination of calves or adults.

For vaccination a living attenuated strain of *Br. abortus*  $\pm 19$  is employed. From the studies which have thus far been made with strain  $\pm 19$  as the immunizing agent against bovine brucellosis, it is reasonable to conclude that when it is used on calves between the ages of four and eight months, sufficient immunity is developed to protect at least 90 per cent against developing brucellosis during the first pregnancy; a high degree of protection remains through the second and third pregnancies; this treatment of calves, nonpregnant heifers, and cows does not lead to the establishment of the injected organism in the animal body; the calves and young heifers show an agglutinin titer for only a few months after vaccination, thus eliminating confusion in the use of the agglutination test as a means of detecting active infection. By the use of such plans and procedures in the United States, the dairy herds in large areas have been rendered brucellosis free.

It has been found practical and economic to maintain herds of swine free from

brucellosis. Hog tight fences for pastures are required. All sows are tested and reactors eliminated. The remaining noninfected sows are bred only with tested boars. Thereafter, brood sows are reared in the protected herd. Similar measures may be employed in the management of goat herds.

## GLANDERS

(Farcy)

Glanders is a widespread communicable disease of horses, mules, asses, and other animals, and is readily communicated to man. Cats may become infected by eating the flesh of glandered horses. Goats also have the disease. Cattle are immune. Guinea pigs and field mice are very susceptible by experimental methods; white mice have a natural immunity. In both man and horses, glanders is remarkable for its fatality. The disease is characterized by the formation of inflammatory nodules either in the mucous membrane of the nose (glanders) or in the skin (farcy). The nodules break down, leaving crater-like ulcers. On the skin the farcy buttons break down and discharge an oily material. The mortality is about 50 per cent. Glanders occurs both as an acute and chronic disease.

The infection may be introduced into the system either through the skin or mucous membrane, and is usually communicated directly from the horse to man by

contact with the infected discharges. The disease is sometimes communicated from man to man. Washerwomen have become infected from the clothes of a patient.

The bacillus of glanders, *Malleomyces mallei*, does not have a spore. It is comparatively frail and readily destroyed by the usual physical and chemical germicidal agencies used against spore-free bacteria. Its resistance corresponds to that of the tubercle bacillus, which it closely resembles in several particulars. The bacillus, however, is frequently protected by albuminous matter or buried in the dirt of stables, water troughs, harnesses and other objects. While the naked germs of glanders are readily destroyed, they are frequently hard to get at; penetration and cleanliness are, therefore, imperative.

The prevention of glanders in man depends primarily upon the suppression of the disease in horses.

**THE MALLEIN TEST.** Mallein is a product of the glanders bacillus corresponding to tuberculin. The injection of mallein into glanderous animals causes a definite rise in temperature and a local swelling about the site of injection, whereas the injection of mallein into normal animals produces no local reaction and very slight if any rise in temperature. The injection of mallein into the subcutaneous tissues (subcutaneous mallein test) has ceased to be used as a practical method for the field diagnosis of glanders, having been supplanted by the ophthalmic and intradermo-palpebral tests. With the mallein test, latent and occult cases of glanders can be diagnosed, but the test must be made and interpreted by an experienced veterinarian else the results may be unreliable.

**Prevention.** When glanders is discovered or suspected among horses in a stable, the horses in the infected stable should be tested. All animals with glanders should be destroyed without further consideration. After these animals have been killed and properly disposed of, the stable should be thoroughly cleansed and disinfected. All other horses which have in any way been associated with the infected animals should be carefully watched and tested again after three weeks, and, should there be no indication of the disease in the second test, the stable may be considered free from the infection; otherwise the infected animals should be destroyed and the tests repeated every three weeks until the disease has been eliminated.

The eradication of glanders from a stable often means considerable loss and sometimes a sacrifice of valuable animals, but it is only through vigorous measures that the disease may be controlled. In the disinfection and cleansing, special attention should be paid to the stalls, harnesses, water troughs, bits, food containers, curry combs, sponges, and other objects exposed to the infection, which is eliminated mostly in the secretions from the mouth and nose. The common drinking trough for horses spreads the infection. The bacillus of glanders is very susceptible to bleaching powder, and it, therefore, is a cheap and reliable germicide for this purpose.

The personal prophylaxis of glanders in man depends upon the education and care of those who have to handle horses. In working with horses known to be infected, rubber gloves, disinfection, and other methods of protection should be employed. Special care should be taken to prevent the spread of the disease through the discharges or by infected fomites from human cases. Fatal accidents have occurred in laboratories in research workers handling pure cultures of *M. mallei*.

## FOOT AND MOUTH DISEASE

(*Aphthous fever, epizootic catarrh, eczema contagiosa*)

Foot and mouth disease is an acute and highly communicable disease, generally confined to cloven-footed animals, and characterized by an eruption of vesicles on the mucous membrane of the mouth and on the skin between the toes and above the hoofs; sometimes on the udder and other parts of the body. The vesicles rupture, leaving superficial erosions which sometimes develop into ulcers. Other symptoms are salivation, tenderness of the affected parts, loss of appetite, lameness, emaciation, and diminution in the quantity of milk secreted. The period of incubation ranges from 18 hours to three weeks. It is usually short, about three to six days.

Foot and mouth disease is primarily a disease of cattle and rarely of man. It also affects hogs, sheep, goats, deer, buffalo, American bison, the camel, chamois, llama, giraffe, and antelope, and even dogs and cats are said occasionally to become infected. Horses and fowl are not susceptible to the infection.

**Causative Virus.** Loeffler and Frosch, in 1898, showed that the virus will pass the finest porcelain filters. This was the first "ultramicroscopic" virus of animals discovered. The first filtrable virus was discovered by Iwanowski in 1892 as the cause of the mosaic disease of tobacco. In 1898, Beijerinck independently arrived at similar conclusions. In the same year, Loeffler and Frosch published their epoch-making studies on the etiology of foot and mouth disease. Their work has been confirmed and extended by many investigators. The virus is recovered and identified by inoculating suspected material intradermally into the plantar pads of guinea pigs. In 24 to 48 hours a primary vesicle develops, and 24 to 48 hours later secondary vesicles appear on the uninoculated pads (Richter, 1938). The virus can be grown in tissue culture. Complement-fixing and virus-neutralizing antibodies can be demonstrated. Three types of aphthous fever virus have been differentiated by cross immunization tests. These types are designated as "A" and "O" (Vallée) and "C" (Waldman). The observations of Trautwein and Reppin (1932), and Daubney (1934) cast doubt on the fixity of these three types. Variant and intermediate types have been observed. Daubney regards the bovine virus as a labile organism subject to spontaneous phase variations. Active immunization using a formalin killed virus vaccine has recently been employed in Denmark, Germany, Mexico, and other countries.

The original experiments of Loeffler and Frosch, as well as experiments which have been made in Denmark and Germany, indicate that the virus of foot and mouth disease is destroyed comparatively readily by heat. Milk pasteurized at a temperature of 60° C for 20 minutes is safe. It is resistant to many of the germicidal chemicals but is destroyed within a few minutes by a 2 per cent solution of sodium hydroxide (lye) (U. S. Agri. Dept., 1928). Field evidence indicates that the virus may remain alive for months on infected premises.

**Transmission.** The virus is contained in the serum of the vesicles; in the saliva, tears, milk, and various other secretions and excretions; also in the blood until the eruption comes out, when it disappears. Some animals after recovery may be carriers for a considerable period of time.

Animals may be infected directly, as by licking; in calves by sucking; or indirectly by fomites such as infected manure, hay, utensils, drinking troughs, railway cars,

animal markets, barnyards, and pastures. The disease is spread largely through persons who care for, examine, milk, or otherwise handle, diseased animals. Veterinary inspectors must take unusual precautions not to spread the infection in their efforts to control it.

Although relatively resistant, man may occasionally be infected through the ingestion of raw milk, buttermilk, butter, cheese, and whey from animals suffering with foot and mouth disease. It may also, though more rarely, be transmitted directly from the salivary secretions or other infected material which gains entrance through the mucous membrane of the mouth. It is doubtful whether the disease can be transmitted to man by cutaneous or subcutaneous inoculations, though it is probable that the infection may be communicated if the virus enters the blood directly through wounds of any kind. Children may be infected by drinking unboiled milk during the time in which the disease is prevalent in the neighborhood; while persons in charge of diseased animals may become infected through contact with the affected parts or by milking, slaughtering, or caring for the animals. The disease is usually mild in man; death practically never results, except in weakened children, and then from secondary complications.

The clinical manifestations of the infection in man are analogous to those seen in animals (Clough, 1915). There are a considerable number of cases described in medical literature (Arkwright, 1928). In relatively few has the diagnosis been verified by animal inoculation or by demonstrating a rise in serum antibody titer.

**Prevalence and Control.** The disease prevails in European countries, especially Russia; also South America, Asia, and Africa, and occasions great economic loss. The mortality is low; the serious losses depend chiefly upon the diminution of the milk secretion and the loss of flesh in the affected animals as well as the disturbances of quarantine. It occurs as widespread epizootics, especially in the warm season.

Foot and mouth disease has appeared in epidemic form in the United States on 10 different occasions: 1870, the eastern states; 1880 and 1884, Massachusetts; 1902, New England; 1908, Michigan; 1914, Chicago; 1924, California; 1925, Texas; 1929, California; and 1932-1933, California. Each of these outbreaks was suppressed through the application of well-known preventive measures, such as isolation, destruction and burial of the affected herds, disinfection, restriction of the movements of cattle, and a systematic inspection of all farms in the infected area to detect cases of the disease. It pays in the end to use prompt and aggressive measures. Even these measures may be inadequate to control the disease under some conditions as has been illustrated by the recent experience in Mexico (Arocha, 1947; Murnane, 1950).

The efforts of the livestock sanitary authorities were successful in keeping foot and mouth disease out of the North American continent from 1933 to 1946. In May of the latter year, a shipment of zebu bulls from Brazil were landed on Sacrificios Island adjacent to Veracruz, Mexico. The animals appeared to be free from foot and mouth disease and after four months' observation were transferred to a ranch in the state of Veracruz not far from the port. Foot and mouth disease appeared among the cattle on this ranch in October. By January, 1947, it had spread widely among the livestock of eight adjoining states of south central Mexico—an area approximately 150 miles from north to south and 300 miles from west to east.

To cope with this threatening situation the Mexican Ministry of Agriculture and the United States Department of Agriculture set up a joint commission and mobilized their scientific, technical, and financial resources. As rapidly as possible, a campaign was organized to stop the spread of the disease by means of the conventional measures of quarantine and slaughter. By the end of April, 1947, about 93,000 animals had been sent to slaughter or slaughtered on the premises. About one half of these were cattle, the remainder being sheep, swine, and goats. In spite of these efforts, by July the disease had spread to eight more states and the quarantine zone extended across the entire central portion of Mexico. The slaughter of animals was proceeding at the rate of 28,000 cattle and 30,000 smaller animals per week. Millions of dollars were paid out to owners in indemnities. By December of 1947, it was realized that to continue the slaughter campaign to its conclusion would require the destruction of most of the animals in the area, estimated as 5,000,000 cattle and an equivalent number of small animals. Mexico could not stand the economic shock of this wholesale destruction plus the disruptions brought about by the quarantine. Even though paid for the destroyed cattle, angry Mexican farmers murdered 23 of the men working in control parties. The program was modified to provide regrouping and concentration of field forces along the north and south quarantine lines; slaughter and burial of infected and exposed animals was limited to a zone a few miles wide along the north and south of these defense lines. Within the infected area it was planned to build up an immune animal population by means of vaccination. A laboratory was set up for the production and testing of vaccines. Eight strains of virus from Mexico were found to be variants of Type A. On the basis of previous work, it was expected that vaccination would afford protection to the inoculated animal for approximately six months. Thus, it was necessary to plan revaccination of herds twice yearly. Later it was found, however, that protection against the disease could not be expected beyond four months from the time of vaccination, so that it became necessary for all susceptible animals in the quarantine zone to be vaccinated at least three times in one year. By the end of November 1949, more than 37,000,000 cattle, sheep, swine, and goats had been vaccinated. Forty outbreaks of Type A virus were discovered during the year, 37 of which appeared prior to June 30th. The remaining three and an isolated case of Type O were exterminated during the last six months. In 1950, it appeared that the situation was under control although it is uncertain as to whether complete eradication had been effected.

## TETANUS

(Lockjaw)

Compared with the major plagues of man, lockjaw has always been a rare disease. It is on account of the characteristic and fatal spasms that it early attracted attention. The spasms are tonic in nature, with acute and painful exacerbations. They usually begin in the muscles of the jaw and neck and in severe cases spread to the voluntary muscles of the body and the extremities, producing opisthotonos.

Tetanus usually occurs sporadically; formerly epidemics in hospitals (especially lying-in hospitals) and in wars were rather common. The conditions of trench warfare in World War I favored wound complications, and included a frightful amount of tetanus until antitoxin was used as a routine prophylactic in all wounded. Before the days of asepsis the infection was often spread through surgical instruments, fingers, bandages, etc.

**Historical Note.** Carle and Rattone, in 1884, first clearly demonstrated the infectious nature of tetanus by inoculating rabbits subcutaneously with pus from a human case of the disease. In the same year, Nicolaier inoculated mice and rabbits subcutaneously with garden earth and saw the tetanus bacillus at the site of injection. In 1889, Kitasato for the first time grew the organism in pure culture, and by successful inoculation experiments proved that this bacillus was the cause of tetanus. Kitasato further showed that the tetanus bacillus is not found in the heart's blood of mice dead of tetanus and, therefore, concluded that we are dealing with an intoxication, and not a bacteremia. We now regard tetanus as a type of the true toxemias; that is, the bacilli remain localized in the wound, and the soluble toxin does the damage. This pioneer work of Kitasato's was of great importance, and led to the epoch-making discovery of Von Behring and Kitasato in the following year (1890) upon tetanus and diphtheria toxins and antitoxins, laying the foundation of serum therapy.

**Etiology.** Tetanus is usually the result of the contamination of a wound by material containing the spores of the tetanus bacillus (*Clostridium tetani*) and the subsequent development locally of anaerobic and other conditions favorable to germination and toxin production. All wounds are not equally liable to this complication. Punctured, lacerated and contused wounds are much more susceptible to tetanus than clean-cut or open wounds. The size of the wound is of much less consequence than its character and content. Fatal tetanus may develop from trivial wounds, such as pin scratches, small splinters, insect bites, vaccinations, etc. Necrotic tissue, foreign bodies, pus infections, and other irritants favor the development of tetanus.

Concomitant infection of a wound with other organisms, particularly of the gas gangrene group (*C. septicum*, *C. perfringens*, etc.) apparently may promote germination of *C. tetani* and toxin formation (Weinberg and Sequin, 1917). Unlike the gas gangrene bacilli, however, *C. tetani* is not invasive. It remains localized in the

wounded area. Frequently, this area is quite small even in fatal cases. Fildes (1929) has emphasized the effect of small amounts of calcium salts in lowering the oxidation-reduction potential of tissue to a level which will permit the germination of tetanus spores.

Tetanus bacilli are frequently present in the wounds of patients who do not develop tetanus. For example, Tulloch (1919) recovered *C. tetani* from 19 of 100 wounds in which there was no evidence of tetanus at the time or at a later period. On the other hand, tetanus sometimes occurs where no wound can be found. This is the so-called "idiopathic tetanus."

Tetanus spores have occasionally been found in the lymph glands, liver and other parts of the body, upsetting our previous view that they are always strictly confined to the site of the wound. The spores may remain latent or dormant in scar tissue or the sequestrum of bone and may be released and start an attack weeks or months afterwards, thus giving a plausible explanation of some cases of idiopathic tetanus.

*Tetanus neonatorum*, or tetanus of the newborn, is still a common and fatal infection in some countries. Before the days of asepsis the infection was permitted to enter through the umbilical wound. In certain of the West Indian islands more than one half of the mortality among the Negro infants has been due to this cause.

The placenta is permeable to tetanus antitoxin. Ten Broeck and Bauer (1923) found that when tetanus antitoxin is present in the mother's blood, it is also present in the cord blood of the newborn infant. This is a prophylactic factor of importance. The colostrum under similar circumstances contains this protective antibody.

**Incubation.** The period of incubation in man is usually from 6 to 14 days. The period is directly proportional to the amount of toxin and the severity of the disease. This can readily be demonstrated upon susceptible animals. In a study of 600 serial tests, Rosenau and Anderson found this direct relation between the period of incubation and the severity of symptoms by the subcutaneous injection of varying amounts of toxin into guinea pigs. Thus, guinea pigs receiving fairly large doses showed symptoms on the third day and usually died; when the dose is smaller, the period of incubation is longer, the disease milder, and the chances of recovery greater. In man, with a short period of incubation, six days or less, the disease is almost invariably fatal. With longer periods, the disease is usually milder and recovery may take place without the use of antitoxin. The incubation period is likely to be prolonged when tetanus develops following a prophylactic dose of antitoxin.

**Occurrence.** The spores are not affected by gastric digestion, and in the intestines of certain animals find ideal anaerobic conditions, food supply and temperature for growth and development. Here they multiply and pass in the dejecta to pollute the soil. The soil, therefore, in all regions inhabited by domestic animals is more or less contaminated with tetanus. The bacilli, however, do not multiply in the soil. While the soil acts only as a vehicle, it is the immediate source of most cases of tetanus in man. The presence of tetanus spores in soil, street dust, fresh vegetables and on clothing and the skin may be traced to fecal contamination.

**IN MAN.** Tetanus spores are present to a variable extent in the intestines of man; claims of their occasional occurrence have long been on record. Those who work in contact with manure are most likely to have them. From 5 to 20 per cent of hostlers and dairymen are "tetanus carriers." Ten Broeck and Bauer (1922) demonstrated tetanus bacilli in 34.7 per cent of the stools of 78 persons in Peking.

These investigators also proved that tetanus bacilli grow and multiply in the intestinal tract of man, because several millions of tetanus spores were found in a single stool of a man kept on a practically sterile diet for a month.

**IN ANIMALS.** The normal habitat of tetanus is in the intestinal tract of animals. The main reservoir of tetanus is probably the digestive tube of herbivora, although the spores may be found in a great variety of animals (Noble, 1915). Park found tetanus bacilli in the intestines of about 15 per cent of horses and calves living in the vicinity of New York City.

**IN THE SOIL.** Tetanus spores are frequently found in manure, cultivated or garden soil. Dubovsky and Meyer (1922) even found the spores in virgin forest soil. They may be blown or carried great distances.

Tetanus spores are not equally numerous in all localities. The infection is much more prevalent in warm than in cold countries. It is especially severe in the tropics, yet Iceland at one time suffered severely from tetanus neonatorum. In the United States, tetanus occurs especially in the Atlantic States, and in some parts of Long Island, New Jersey, and the Hudson Valley, which have become noticeable for the number of cases of tetanus complicating small wounds. The soil of the western states is relatively free from this anaerobe. The soil of Flanders and France has through long cultivation become saturated with the spores of tetanus and other anaerobes. One grain of it from the trenches injected into a laboratory animal invariably produced tetanus. Tetanus spores are widely disseminated in India.

**MISCELLANEOUS.** On account of the great resistance of the spores, they are blown about in dust and are spread everywhere by dirt and manure. Tetanus has been found in hay dust, on horses' hair, in the dust of houses, barracks, and hospitals, in the mortar of old masonry, in street dust, on food, in gelatin, on the skin, and in the greatest variety of places.

One of the agencies in the distribution of tetanus spores over limited areas is undoubtedly the common housefly. The poisoned arrowheads of certain savages in the New Hebrides contain tetanus spores obtained by smearing the arrowheads with dirt from crab holes in the swamps (Le Dantic).

Tetanus spores or toxin may contaminate bacterial vaccines, antitoxic sera, vaccine virus, and other biologic products used in human therapy.

A test for tetanus spores is now required by the United States law of July 1, 1902, for all sera and vaccines sold in interstate traffic. As a further precaution against this complication horses undergoing treatment for the production of immune sera are given prophylactic doses of tetanus antitoxin from time to time.

It is, of course, not the rust on a nail that is dangerous, so far as tetanus is concerned, but the spore-bearing dirt it carries into the deep, contused wound that causes the trouble. Gelatin may contain tetanus spores, and the subcutaneous injection of imperfectly sterilized gelatin as a hemostatic has sometimes resulted in accidents.

**Resistance of Organism.** The tetanus *bacillus* is readily destroyed by the ordinary agencies that kill vegetative bacteria. It is killed almost at once in contact with the free oxygen of the air. On the other hand, few, if any, forms of life have a greater resistance than the tetanus *spore*.

The experimental results are sufficiently varied and conflicting to suggest that races of tetanus bacilli exist, the spores of which vary widely in their resistance to

moist heat at 100° C. Theobald Smith (1908) found that under certain conditions of sterilization some tetanus spores survive a single boiling or streaming steam regularly for 20 minutes, usually for 40 minutes, and occasionally for 60 minutes; in one case 70 minutes' exposure did not destroy the spores. He also showed the possibility of tetanus spores surviving in culture fluids sterilized by discontinuous boiling or steaming in routine laboratory work for fully 20 minutes on three successive days.

In general, dry spores are more resistant than moist spores; and young spores are often harder to kill than old spores.

Tetanus spores resist the action of 5 per cent carbolic acid for 10 hours, but are killed in 15 hours. A 5 per cent solution of carbolic acid, however, to which 0.5 per cent of hydrochloric acid has been added, destroys them in two hours. Bichloride of mercury 1:1,000 kills the spores in three hours, and in 30 minutes when 0.5 per cent of hydrochloric acid is added to the solution. According to Park, silver nitrate solution destroys the spores of average resistance in one minute in 1 per cent solution, and in about five minutes in a 1:1,000 solution. *Tetanus spores are destroyed with certainty when exposed to dry heat at or above 160° C for one hour, or to steam at 120° C for 20 minutes. Entire confidence may be placed upon either of these two methods, provided there is direct exposure.*

Direct sunlight does not kill the spores, but seems to diminish their virulence. Under certain circumstances they may live a long time; Henrijean reports that, by means of a splinter of wood which once caused tetanus, he was able after 11 years again to cause the disease by inoculating an animal with the infective material.

**Frequency of Disease.** Since reporting of tetanus is incomplete, mortality records furnish the best indication of its prevalence. Changes made in 1938 in the assignment of priority of causes of death render mortality statistics subsequent to that year deficient for this disease. Prior to that time, deaths from tetanus arising from injuries were included, but deaths from tetanus following surgical operations, abortions or childbirth were not counted as such. With this in mind, Table 9-1, based on the United States Census Bureau Mortality Reports for the years 1934-1938 inclusive, will give some idea of the distribution of mortality by age, sex, and

Table 9-1. Tetanus mortality in the United States, 1934-1938 (exclusive of deaths from tetanus secondary to surgical operations, pregnancy, childbirth and the puerperium)

Age Group	Number of Deaths in 5-year Period				Average Mortality Rate per 100,000 Estimated Population Per Year			
	White		Nonwhite		White		Nonwhite	
	Males	Females	Males	Females	Males	Females	Males	Females
Under 1	252	167	237	144	5.36	3.69	39.17	23.48
1-4	185	112	53	27	.94	.59	2.00	1.01
5-14	900	340	247	93	1.73	.67	3.61	1.35
15-24	342	85	107	51	.76	.16	1.74	.74
25-34	166	76	106	34	.37	.16	2.07	.60
35-54	399	177	164	91	.53	.25	2.14	1.20
55 and over	397	176	77	22	.95	.43	2.41	.77
All ages	2,641	1,133	991	462	.91	.40	3.07	1.40

race at that time. This table shows that males had higher mortality than females at all ages, averaging a little over twice as high; that mortality was considerably higher in the nonwhite population; and that deaths under one year of age (presumably consisting almost entirely of tetanus neonatorum due to umbilical cord infection) are the greatest problem. The great difference from mortality from tetanus in infancy between the white and the colored populations is especially noteworthy and presumably due to unhygienic practices in the care of the cord in the latter group. Exclusive of infancy, the period of later childhood presents the highest risk of mortality, although age differences are not marked.

**Prophylaxis.** Following Ramon's discovery of a method of detoxifying diphtheria toxin by tormalin, Descombey (1924) produced a tetanus toxoid. Ramon and Zoeller (1933) suggested the employment of this agent in active immunization of man. It was pointed out by d'Antona and Valensin (1937) that active immunization of guinea pigs afforded a more effective protection against injected toxin than did passive immunization.

Since 1933, toxoid has been employed on an ever increasing scale, World War II providing a large impetus to its use. Active immunization has been administered to exposed groups and in pediatric practice, followed by stimulating injections at various intervals and by "emergency booster" doses after injury. A number of workers have investigated blood antitoxin titers after active immunization. Bigler (1951) has reported detectable amounts of antitoxin in the blood of children tested up to 10 years after administration of two or three injections of toxoid. A sharp rise in titer occurred within one week after a booster dose.

The U. S. Armed Forces have actively immunized all personnel with tetanus toxoid since 1941. Until 1949, the Army and Air Forces employed fluid toxoid, while the Navy used alum-precipitated toxoid; now all of the services use the latter.

The routine procedure in the Army during World War II consisted of giving three subcutaneous injections of 1 ml. of fluid toxoid at intervals of three weeks upon enlistment, with a "routine" stimulating dose of 1 ml. a year later. Until 1944, additional doses were frequently administered to troops likely to enter active combat; this was probably unnecessary. An "emergency" stimulating dose was given to all previously immunized persons who sustained wounds, burns or injuries thought to carry a hazard of tetanus. A record of the dates of basic immunization and the routine stimulating injection was made on each soldier's metal identification tag; tetanus antitoxin was given to wounded men only if they did not possess such a record. The procedure with alum-precipitated toxoid was the same except that an initial series of only two doses of 0.5 ml. one or two months apart was required.

World War II provided a test of active prophylaxis just as World War I had demonstrated the value of prophylactic antitoxin. Long and Sartwell (1947) report that 12 cases of tetanus occurred among Army and Air Forces personnel in World War II, five of which were fatal. Of these 12 cases, six had received no active immunization (these men had not been in the service long enough to receive toxoid); two had received the basic series but no emergency stimulating dose; and the remaining four had been fully immunized. Only one of the 12 cases resulted from wounding in battle (there were about 600,000 such wounds). Mortality from tetanus in the Army amounted to 0.02 deaths per 100,000 troops per year; the United States mortality rate for white males, aged 15 to 34, in the period 1934 to 1938, was

0.52 per 100,000, a figure more than 20 times as high. The contrast is especially remarkable in the light of the fact that there is a vastly greater hazard in military services of injuries which might lead to tetanus.

The Navy had an equally favorable experience, as reported by Hall (1948). During World War II there were four cases of tetanus with two deaths, only one being in a fully immunized person.

Tetanus prophylaxis in the British Armies differed somewhat from that described above, especially in that actively immunized men who sustained injuries were given antitoxin instead of toxoid. Boyd (1946) states that during the war period there were 35 cases of tetanus due to battle injuries among British and Colonial troops, of whom 16 had not been actively immunized. Eighteen additional cases occurred following nonbattle injuries.

From accounts of the amount of tetanus in wounded German and Japanese troops, as well as civilians wounded in military operations, there can be no doubt that this disease would have taken a high toll of lives had our forces not been protected.

While all reports have indicated the efficacy of toxoid, passive protection with antitoxin is also effective. The use of toxoid offers two advantages: first, it provides at least some protection, as pointed out above, against the risk of tetanus following minor injuries which do not require or receive medical attention; and second, it eliminates the need for administration of antitoxin, an agent which contains horse serum and, therefore, carries a definite risk of serum sickness or anaphylactic reactions, particularly on repeated use. While some immediate reactions of sensitivity to toxoid were reported by Long (1943) and attributed to the type of peptones contained in the culture media, such reactions became extremely rare after the use of toxoid containing these peptones was discontinued. Thus, toxoid can be administered repeatedly with practically no hazard of serious reactions.

The question of how widely to employ routine active immunization is receiving considerable attention. Press (1948) has discussed the pros and cons. His summary of the findings of eight investigators who studied the types of injuries preceding onset of tetanus is of interest. These eight series ranged in size from 25 to 352 cases, and the percentages of cases giving no history of injury varied from 10 to 46 per cent. From 20 to 53 per cent of cases in the different series gave a history of only trivial injuries; many of the latter were so trivial that medical attention would not have been sought for them (examples are infected insect bites, and superficial cuts and scratches). The high relative frequency of cases with no known injury or minor injury is undoubtedly related to the practice of administering antitoxin for more serious wounds, thus reducing the number complicated by tetanus, as well as to improvements in surgical technics; yet it appears that there is little hope of much further reduction in the incidence of tetanus without resorting to active immunization. Active immunization will prevent these cases resulting from trivial wounds only if, as seems probable, it is unnecessary to give toxoid at the time of the injury to the basically immunized person.

Pratt (1945), in a study of 56 cases in children, included in the summary by Press, pointed out that 11 cases (20 per cent) had had injuries that usually would be treated by a physician, and that many physicians would feel warranted the use of antitoxin or toxoid. Another 20 per cent had injuries so trivial that medical

attention would seldom be sought; if treated by a physician tetanus antitoxin would probably not be employed, although a booster shot of toxoid might be given if the patient had previously been actively immunized. The third group (34 cases, or 60 per cent) represented types of injury in which it is most improbable that either antitoxin or booster injections of toxoid might have been used. Of these 34 cases, 16 (29 per cent of the entire series) gave no history of injury; seven followed vaccinations; five followed minor cuts on the hand; five were due to umbilical cord infection and one resulted from a boil on the leg.

One obstacle to the full utilization of the advantages of toxoid over antitoxin is the fact that the physician treating an injured patient often cannot determine whether his patient has been actively immunized. This disadvantage does not exist in military medical practice; every soldier is routinely immunized shortly after enlistment and, in addition, his identification tag, which is worn at all times, and his immunization register both carry entries indicating the dates of immunization. Under civilian conditions, a record of immunizations is frequently not available and an injured person often cannot give a reliable statement to the doctor on this point. Thus, it becomes necessary to give antitoxin with the attendant hazard of reactions despite the fact that the patient has been actively immunized. Tattooing patients with a symbol to indicate that they have received full immunization might be suggested but it is doubtful whether this would be acceptable. Some means should be found in these days of extensive travel, accident hazard, and possible civil participation in the fruits of war to ensure the availability of information concerning each person's blood group and immunization status.

**LOCAL TREATMENT OF WOUNDS.** Surgical treatment of the wound as soon as possible is the first important measure in the prevention of tetanus. Wounds, however insignificant, should be thoroughly cleansed. Punctured or lacerated wounds, in which there is special danger of tetanus, should be freely opened, and every particle of foreign matter carefully removed. Promptness in cleansing the wound surgically is almost as important as thoroughness. Gunshot wounds and wounds containing garden earth, street dust, or other material liable to contain tetanus spores should receive special consideration. All necrotic tissue, or tissue likely to die, must be removed. The experience of World War I demonstrated that thorough excision of the wound (*débridement*) is good practice. Ordinary germicides are useless. Iodine within three to four hours after injury may be effective for organisms still on the surface. The surgeon's knife is the best antiseptic. The division of the umbilical cord and the treatment of the navel in the newborn must be done under the strictest asepsis. Wounds in which there is suspicion of tetanus should be kept open and freely drained and otherwise treated so as to discourage anaerobic conditions.

**PASSIVE IMMUNIZATION.** Tetanus antitoxin is a specific and trustworthy preventive. The great experience of World War I adds confirmation to the protective power of this specific serum. Its use, however, must be understood to achieve satisfactory results. The antitoxin should be administered before the advent of symptoms, for after the tetanus toxin has combined with the motor nerve cells in the central nervous system, it is displaced or neutralized with difficulty, if at all. As with other antitoxins, a small amount given early is better than great quantities later. It is, however, practical to give antitoxin to the point of saturation in the disease. This is

done with the knowledge that it will fix and neutralize the free toxin and thus prevent further damage, and with the hope that it will dissociate some of the poison combined with the central nervous tissue. After symptoms have commenced, large doses should be given intravenously and subcutaneously as well as into the spinal canal and into the nerves leading from the wound.

The standard prophylactic dose of tetanus antitoxin has been considered to be 1,500 U. S. A. units (3,000 International units). Certain investigators believe this to be too little and suggest a dosage of 10,000 to 20,000 units, the larger amount being reserved for severe injuries or cases where seroprophylaxis is delayed. In cases where a tetanus hazard is considered to be still present, as in wounds containing necrotic tissue or a foreign body, or after secondary operations, administration of a further dose after one or two weeks may be indicated, care being taken to avoid anaphylactic reactions from sensitivity developing after the first dose. Since antitoxin contains horse serum, patients must always be tested for sensitivity prior to the injection and those who are sensitive cautiously desensitized. Active immunization may be initiated in patients who have been passively immunized, the findings of Cooke and Jones (1943) suggest that it is best to wait two to four weeks or longer after giving prophylactic antitoxin before beginning the series of toxoid injections, since the development of active immunity appears to be inhibited when there is considerable antitoxin in the blood resulting from passive immunization.

## RABIES

*(Hydrophobia)*

Rabies is an acute, specific, rapidly fatal paralytic infection communicated from a rabid animal to a susceptible animal, through a wound usually produced by biting. Man always contracts the disease from some lower animal, commonly the dog. Rabies belongs to the group of virus diseases. The virus is harmless when ingested provided the mucosa is intact. *Rabies is a wound infection.*

The disease is remarkable in several particulars, especially the period of incubation, which is more variable and more prolonged than that of any other acute infection, and its high mortality, which is practically 100 per cent. Spontaneous recovery from rabies naturally acquired is rare if it occurs at all.

**Prevalence.** Rabies has been known since the dawn of civilization. Stone murals from ancient Rome, Greece, and Egypt depict mad dogs; Greek mythology has reference to the disease. Gradually, its world-wide distribution was realized. A few geographically isolated areas remained free—Australia, Hawaii, and some of the smaller islands.

In Europe, during the eighteenth and nineteenth centuries, there were widespread epizootics of canine rabies suppressed in local areas from time to time by rigid dog control measures. In 1815, rabies appeared for the first time in Denmark and Norway, and in 1824 in Sweden. It was quickly eliminated from these countries and they have remained free from the disease to the present time. In England, the incidence of rabies in man and animals during the nineteenth century fluctuated with periods of enforcement and relaxation of dog control measures. It was completely eradicated by 1903 and quarantine regulations to prevent importation have been rigidly enforced since that time. Although reintroduced in 1918 by a dog carried over from the continent by plane, it was again free by 1921 and has remained so.

The earliest account of rabies in North America was in 1768 when the disease appeared in the vicinity of Boston. From this focus it gradually spread with the settlement of the country. By 1900 it was enzootic over most of the United States. Several major outbreaks of rabies in wild animals have been recorded. Notable are the epizootics in skunks (Kansas, 1875; Arizona, 1907-1910), in coyotes (Nevada, Oregon, California, 1915-1916); in foxes (Massachusetts, 1812; Alaska, 1915). Between 1937 and 1944 fox rabies was reported in 20 states (Johnson, 1945a). Whenever wild canine species, such as the fox and the coyote, are allowed to become abundant in an area there is a constant threat that rabies will become prevalent.

The preponderance of infections in animals with this virus in the United States is, of course, in dogs. In this species it maintains its transmission from year to year and from place to place in most of the states of this country with periods of regional increase and decrease. In 1945, 14 states reported to the Federal Department of Agriculture that they had had no rabies in either animals or human beings; this group included the New England and eight western states. Although the number of human beings who die of rabies each year is relatively small (25 to 50 in the U. S. Registration Area), approximately 30,000 persons receive rabies vaccine treatment each year.

**Seasonal Distribution.** There is an old superstition that rabies is prevalent

Table 9-2. Number of cases of rabies in man and animals reported in the United States, 1938-1949 \*

Year	Dogs	Cattle	Horses	Sheep	Swine	Cats	Goats	Miscellaneous	Man	Total
1938	8,452	413	32	164	42	207	11	44	47	9,412
1939	7,386	358	36	17	38	269	10	172	30	8,314
1940	6,194	326	25	53	71	260	4	277	28	7,238
1941	6,648	418	39	68	159	294	9	212	30	7,877
1942	6,332	288	15	48	32	250	12	160	28	7,165
1943	8,515	349	35	45	60	316	19	310	41	9,690
1944	9,067	561	32	40	43	419	14	311	53	10,540
1945	8,505	487	46	11	30	466	10	373	35	9,963
1946	8,384	962	44	15	22	455	12	956	22	10,872
1947	6,949	766	40	15	20	393	9	728	26	8,946
1948	6,610	599	34	14	36	378	5	819	13	8,508
1949	5,237	639	24	22	54	413	6	1,192	10	7,597

\* Figures from the Bureau of Animal Industry, U. S. Department of Agriculture. (Miscellaneous other animals include mostly wild species such as foxes, wolves, coyotes, skunks, etc.)

during the hot summer months. However, it has been found from repeated analyses that the incidence is fairly uniform throughout the year, with some seasonal increase in the late winter or early spring. This may well be due to the fact that the stray dog, wolf, and fox range more widely during these months in search of food and mate. Epizootics of rabies may occur at any time of the year.

**The Disease in Dogs.** A normal dog that is bitten by a rabid animal may develop rabies in as short a time as 10 days, or it may show no symptoms until several months later. In most instances, rabies will develop from 21 to 60 days after exposure. The virus is not present in the saliva until the early symptoms of the disease appear.

Rabies in dogs is usually classified as furious or dumb, depending upon the symptoms shown by the animal.

**FURIOUS RABIES.** During the early stage of the disease, a dog may appear quite normal and be even more affectionate than usual. Despite its friendly actions the dog will be easily irritated, especially if restrained in any way. If picked up, it will immediately try to break away and, if not promptly freed, will bite savagely. This is usually the way children are bitten, because they will pick up a friendly looking dog and try to hold it when the animal attempts to get away. Restlessness and excitement are other early symptoms that will be shown by the dog. The dog will seldom be still for more than a moment and will snap at flies and chase chickens, cats, and domestic animals. It also will have a tendency to eat sticks, straw, earth, and other indigestible material. After a period of one to three days, the dog may become extremely vicious and will bite any living thing that gets in its way, including its master. The eyes will be glazed and constantly wide open. Often there will be a peculiar howl-like bark. During this stage, the dog will usually wander away from home, roam the countryside, and attack any person or animal it sees. Within a few days paralysis will develop, first shown by a wobbly or staggering gait. Paralysis will then extend until the animal cannot get up. Dogs with this type of the disease usually live several days and may live as long as 11 days after developing symptoms.

**DUMB RABIES.** In this type of the disease, the early symptoms consist of sleepi-

ness and melancholia; the dog will try to hide or get away by itself. These symptoms are soon followed by paralysis of the jaw, throat, voice and leg muscles. There will be no irritability or tendency to bite, but persons may be exposed to rabies by trying to look at the animal's throat or while giving medicine. Animals so affected seldom live more than three days after developing symptoms.

In most cases, rabid dogs show symptoms of both types of the disease, that is, a period of restlessness, excitement, and irritability, during which they appear friendly and unusually alert, followed by rapid progression to paralysis of the dumb rabies type. Some animals affected with rabies die suddenly without showing any symptoms of illness. In other instances, the first symptom is a convulsive seizure during which the animal may die.

It is to be noted that dogs and other animals suffering from rabies are without fear. Rabid wild animals, such as foxes and skunks, will fearlessly invade farm premises and attack persons, dogs, and domestic animals in daytime. The disease makes them insensible to pain, and blows or gunshot will not frighten them.

**Conditions of Transmission.** Transmission of the disease depends primarily upon localization and excretion of the virus from the salivary glands. Usually, it appears at about the time of onset of the prodromal symptoms. Several investigators have reported finding the virus occasionally present in the saliva of dogs from 4 to 14 days before the appearance of the disease. It is, therefore, sufficient to watch for 14 days a dog that has bitten a person, and if no symptoms of rabies appear in the dog during that time, there is no danger of conveying the disease and the Pasteur prophylactic treatment is unnecessary. Fourteen days has a factor of safety. Practically, the danger from a bite during the preclinical stage of the disease is slight. While it is possible that dogs in rare instances may develop an abortive type of rabies and recover, it is extremely unlikely that the animal so affected will have the virus in its salivary glands (Johnson, 1943). There is at present no evidence to indicate that the dog can act as a symptomless carrier of rabies.

The development of rabies following exposure to a rabid animal depends upon a number of other factors. The bites of horses and other herbivora are less dangerous than are the bites of wolves, dogs, foxes and other members of the canine species. Of great importance is the nature of the wound. The more the skin and underlying tissues are lacerated the greater the danger of infection. Bites on exposed surfaces are more dangerous than through clothing, since in the latter case the saliva may be wiped off and little or none enter the wound. Long haired dogs and sheep often escape infection for the same reason. This accounts, at least in part, for the differences due to location of the bite. For example, Dobert noted that 12 cases of rabies developed among 118 persons bitten on the head (10 per cent), 24 cases among 1,251 persons bitten on the arms (2 per cent), one out of 564 bitten on the legs (0.2 per cent) and no cases among 72 bitten on the trunk. Occasionally, an individual is infected with rabies by exposure to the licking of the skin by a rabid animal. In these instances, it is assumed that there exists a minute abrasion through which the virus makes contact with nerve endings.

Because of these many variables, it is impossible to estimate accurately the risk of rabies to an individual who is exposed to a rabid animal. Such information as is available comes principally from the time period before prophylactic treatment by vaccination was introduced and before the diagnosis of rabies was confirmed by

laboratory examination. For example, Faber reported that only 36 (6 per cent) of 597 persons bitten by rabid animals developed rabies. Kirshner of Prussia recorded 38 deaths (3 per cent) among 1,453 persons bitten by rabid dogs. Schuder noted only 1,325 deaths (9 per cent) in a group of 14,959 persons bitten by rabid animals. These and other observations coming down from this period, suggest that a great majority of individuals exposed to a rabid animal escape infection even though they are not given prophylactic treatment with vaccine.

**Period of Incubation in Man.** There is still some doubt as to the route by which the virus travels from the injured tissues to the central nervous system. The balance of evidence indicates that the virus travels predominantly by way of the sensory nerves. Ability to infect animals by means of a scratch on the cornea or skin supports this theory. The blood stream and the perineural lymphatics do not appear to play any significant part in the invasion or propagation of the virus. Rabies virus, however, is not strictly neurotropic. Submaxillary glands are the best source of virus aside from the central nervous system. Concentration of the virus in these glands is often as high as that in the brain.

In man, the average incubation period is 42 days. Rabies may develop as early as 10 days after exposure. Incubation periods of over 90 days are relatively rare. In Harald Johnson's experience with 137 cases of human rabies, the longest incubation period was 210 days. The average incubation period for children developing rabies is shorter than for adults. Experimental studies show that the amount of virus introduced and the type of tissue exposed influence the duration of the latent period. Temporary arrest of virus multiplication may occur either at the site of infection or at some place in the nervous system.

**Diagnosis.** The diagnosis of rabies (Johnson and Sellers, 1948) is based on the consideration of as many of the following factors as are available: history of exposure, clinical symptoms and course, termination of illness, microscopic demonstration of Negri bodies in the brain, and inoculation of experimental animals with emulsions of brain tissue. Of these, the first and second are of the utmost importance in consideration of the necessity of arriving at a decision in the shortest possible time. To this end, it should be emphasized that when an animal is suspected of having the disease it should not be killed immediately but, if possible, apprehended and confined under observation of a veterinarian for at least 14 days. Ordinarily, the animal will succumb within five days if it has rabies.

The specimen submitted to the laboratory for the confirmation of diagnosis is the head of the suspected animal. It should reach the laboratory in as fresh condition as possible, using refrigeration if necessary in shipment. The brain should be removed with aseptic precautions. The specific intracytoplasmic inclusion (Negri) bodies when present are readily demonstrated in smears or impressions made from the Ammons horn of the brain, stained with Seller's carbofuchsin, methylene blue, or some other similar method. A positive microscopic diagnosis is sufficient for the diagnosis of rabies. However, only about 90 per cent of the proved rabid dogs have Negri bodies in the brain. The finding depends upon the duration of the disease before the animal is killed or dies of rabies. Therefore, if the microscopic examination of a brain specimen is negative, it is necessary to use animal inoculation in order to establish the diagnosis.

For this purpose, a mouse test developed by Webster and Dawson is in general

use. The advantages of the mouse are: its low cost, making possible the use of several animals for testing one specimen; the relative short incubation period of rabies in the animal; and the consistency of the production of Negri bodies in the brains of mice inoculated cerebrally with rabies virus. It is preferable to use mice between three and six weeks of age. A 10 per cent emulsion of the suspected brain tissue is prepared in normal saline, centrifuged at 2,000 r.p.m. for 5 or 10 minutes and the supernatant fluid used for the test inoculation. A dose of 0.03 ml. is injected intracerebrally by means of a tuberculin syringe, using at least four mice for each specimen. If a specimen is positive, some of the mice usually show symptoms between the sixth and eighth day after inoculation. After the development of symptoms, Negri bodies are usually numerous and can be found throughout the brain. In routine mouse inoculation tests, surviving mice are ordinarily discarded and destroyed on the thirtieth day following cerebral inoculation.

**Prevention.** The prevention of rabies is considered under three heads: (1) treatment of the wound; (2) the Pasteur prophylactic treatment; and (3) the control of the disease in dogs.

The cauterization of the wound and the Pasteur prophylactic treatment are efficient preventive measures for the individual, but they are not the true methods of controlling and preventing the disease. Rabies may be checked, even eliminated, by measures directed toward the dog.

**Local Treatment of the Wound.** CAUTERIZATION WITH NITRIC ACID. Wounds produced by the bite of an animal, in which there is any possibility of rabies, should at once be cauterized with "fuming" or strong nitric acid. The acid is best applied with a glass rod thoroughly to all parts of the wound, care being taken that pockets and recesses do not escape. Punctured wounds should be laid open to allow proper cauterization. Rosenau's experiments indicated the importance also of cauterizing the edges of the skin.

Thorough cauterization with nitric acid reduces the danger of wound complications, and experience demonstrates that wounds promptly and thoroughly cauterized with nitric acid are seldom followed by rabies. Cabot obtained the best results with nitric acid and was able to save the lives of 91 per cent of guinea pigs by cauterization with nitric acid at the end of 24 hours; Poor saved 45 per cent at the end of 22 hours. Experiments under Rosenau's supervision (unpublished) indicate that practically all guinea pigs may be saved by prompt application of nitric acid; that its effectiveness decreases with time, but that it is still partially protective up to 48 hours. Strong germicides, such as carbolic acid, are not reliable; nitrate of silver is valueless; formalin and the actual cautery are not effective. Recently Shaughnessy and Zichis (1943) have compared the effectiveness of nitric acid, 20 per cent green soap solution, and tincture of iodine for the treatment of wounds in infected guinea pigs. They found that the green soap solution was as effective as nitric acid where the treatment was carried out within two hours after exposure. Tincture of iodine was less effective.

**Pasteur Prophylactic Treatment.** This method was announced December 6, 1883, by Pasteur, at the International Congress at Copenhagen, and on February 24, 1884, he laid before the French Academy the details of his experiments and results. The next year Pasteur, with the help of Roux and Chamberland, worked out the details of the method, modifications of which are now in general use.

The principle of the treatment consists in producing an active immunity by means of a modified virus, which is attenuated by drying. The fixed virus contained in the spinal cord of rabbits dead of hydrophobia is emulsified and injected subcutaneously.

The distinction between street and fixed virus is of fundamental importance with reference to immunity.

**STREET VIRUS AND FIXED VIRUS.** *Street virus* refers to the virus as it is found in nature. It was so called by Pasteur because he obtained it from mad dogs brought in from the streets of Paris. When this virus is inoculated subdurally into a rabbit, the disease is reproduced after a variable and often prolonged incubation period, 14 to 21 days or more. If the virus is then conveyed from rabbit to rabbit through a series of transfers, it becomes progressively more virulent for rabbits. The period of incubation is shortened, until finally the rabbits invariably sicken on the sixth or seventh day and die on the ninth or tenth. When the virus has reached this degree of virulence for rabbits, it is said to be *fixed* for the reason that its virulence remains constant. In its passage through rabbits the modification from street virus to fixed virus is gradual. It is important to note that fixed virus, which has attained a high degree of virulence for rabbits, has lost much of its potency for dogs and seems to be avirulent for man when introduced into the subcutaneous tissue.

*Fixed virus* is cited as an example of "mutation" of a pathogenic micro-organism by animal passage. The morphology of the Negri bodies is altered, and according to Levaditi fixed virus has lost the special pansporoblastic cycle of evolution represented by the Negri bodies. Pasteur showed that the virus may be intensified by successive passage through certain animals, as guinea pigs, rabbits, and cats; and weakened by passage through other species, as monkeys, etc.

The subcutaneous tissue is evidently resistant to the fixed virus; indeed, even when street virus is injected subcutaneously into susceptible animals the results are uncertain. Marx tested the fresh fixed virus upon monkeys in large doses with negative results. Levaditi reproduced the disease in a chimpanzee intracerebrally. Many hundreds of thousands of persons have been injected subcutaneously with the fixed virus since 1884, when Pasteur announced his discovery, with satisfactory protection against rabies and without untoward effects. It is suggested, however, that the fixed virus may occasionally be pathogenic for man when injected subcutaneously in view of the paralysis which sometimes complicates the Pasteur prophylactic treatment, but the interpretation of these cases is not settled.

**Preparation of the Virus.** Rabbits are injected under the dura mater with a few drops of an emulsion of fresh fixed virus. Strict aseptic precautions are necessary in order to keep out other infections. The rabbit should begin to show symptoms on the sixth or seventh day, and die on the ninth or tenth. Usually the rabbit is not allowed to die, but is chloroformed in order to avoid terminal infections and unnecessary suffering. The spinal cord is removed and hung in a bottle containing potassium hydroxide, and kept in the dark at a temperature of 22° C. Under these conditions the cord dries, and at the same time the virulence of the virus diminishes until it is no longer infective.

Pasteur was well on the safe side in starting treatment with cord 14 days old;

in fact, the virus dies long before the fourteenth day; five-day cord usually fails to infect, and eight-day cord has lost its power of producing the disease.

About one-half a centimeter of the cord constitutes a dose. This is ground in about 2.5 ml. of sterile salt solution so as to produce a uniform emulsion, and strained through gauze. This suspension is injected into the subcutaneous tissue of the abdominal wall. Pasteur began with cord 14 days old and gradually worked up to cord three days old. The injections were given daily for a period of 18 days (mild treatment) or 21 days (intensive treatment). The dosage is approximate and the scheme of injection somewhat elastic and gradually has undergone modification.

Bacteriologic examinations are made of parts of the spinal cord in order to insure the absence of bacteria, and the rabbit is carefully autopsied as a guarantee that no other disease is present.

**OTHER METHODS.** The classic schema of Pasteur has been modified in various ways to attenuate, inactivate or control the dosage of fixed virus contained in nervous tissue emulsions or extracts. Instead of drying infected rabbit spinal cords, Höyges obtained a similar result through serial dilution of an emulsion of active material and Babes through a 15-minute exposure to temperatures ranging from 80° to 45° C. Harris introduced desiccation from the frozen state. Many investigators have shown that fixed virus inactivated in the presence of phenol retains its capacity to immunize (Semple and others). Vaccines have been developed in which virus is inactivated by formalin (Cumming), ether (Remlinger), chloroform (Kelser), ultraviolet irradiation (Hodes and others), and mustard compounds (Ten Broeck and Herriott).

The development of a mouse test (Habel, 1940) for assaying the potency of rabies vaccine has resulted in improvement in production. Rabies vaccine distributed by commercial biological laboratories in the United States for immunization of man and animals must pass a prescribed test.

*The Semple Method.* The Semple method is fast becoming the method of choice on account of its simplicity and apparent effectiveness.

The material for the prophylactic injections is prepared from the fresh fixed virus in the brain, medulla and spinal cord of rabbits. An 8 per cent suspension of the brain, medulla and cord is made by grinding it up in sterile normal saline containing 1 per cent carbolic acid. This is strained through fine muslin and kept at 37° C for 24 hours. At the end of this period the virus is dead; at least it is not infective when injected into susceptible animals. The material is now diluted with an equal volume of sterile normal saline solution. This final dilution contains 4 per cent of the virus material in 0.5 per cent carbolic acid normal saline solution. The dose is 2.5 ml. injected into the subcutaneous tissues of the abdominal walls once a day for 14 days.

The claim for the Semple method is that the suspension retains its maximum potency and powers of immunization for a period of at least three months. The material injected contains the smallest amount of nerve tissue commensurate with efficient treatment. The dosage is more accurate than with the attenuated cord method, since the cords vary greatly in size. The Semple method is economical and further convenient as the vaccine may be produced in quantity and the whole treatment sent in one shipment. All doses of the vaccine are the same, regardless

of age, sex, severity of the bite or location of the wound. On account of the danger from bites on the face and multiple bites there is a tendency to give more intensive treatment in these cases.

**CARE DURING TREATMENT.** Rigid precautions are not necessary. During treatment the patient may go about his usual business. It is not necessary to stay in bed.

**COMPLICATIONS OF TREATMENT.** The complications are (1) local reactions or (2) paralysis.

*Local Reactions.* Local reactions at the site of the wound are usually trivial. Abscesses do not occur. The local reactions consist of redness and induration. It is not necessarily the last injection, but rather the site of some previous injection that flares up, but soon subsides without further trouble. This occurrence increases with the progress of the treatment; it is most frequent in the second week. As the treatment involves the introduction of foreign proteins into the body, it is probable that these reactions are explained in term of allergy.

*Paralysis.* Paralysis, when it occurs, comes on during or shortly after the treatment. It usually consists of brief weakness of limited groups of muscles affecting the extremities or the face. Sometimes the complication is neuritic and occasionally paraplegic. Exceptionally, the paralysis is of the ascending or Landry's type and ends fatally when it affects the muscles of respiration. It is not easy to differentiate between this complication and true paralytic rabies which may occur during the course of treatment.

Acute encephalitis caused by vaccine is characterized by high fever, delirium, convulsions and coma which may terminate in death. Nonfatal cases ordinarily recover without sequellae. This type of reaction is thought to be due to specific sensitiveness to brain material (Rivers and others, 1933; Morgan, 1947; Kabat and others, 1947). Experimentally, Habel and others (1949) have been able to remove from rabies vaccine by chemical extraction the factor which causes this allergic encephalitis.

Many estimates have been made of the risk of postvaccinal paralysis. The complication occurs following all the different modifications of the Pasteur treatment. Its frequency is best indicated by the reports on antirabies treatments supplied by Pasteur institutes to the Health Section of the League of Nations. Greenwood (1945-1946), summarizing the experience from his own and nine previous reviews of McKendrick, and taking into consideration all forms of treatment, estimated the risk of postvaccinal neuromuscular accident to be 1:5,814. Approximately one in four was fatal—a treatment fatality rate of 0.004 per cent. Experience in the United States is indicated by two recent reports. Sellers (1947) recorded seven cases of vaccine paralysis among approximately 50,000 with a phenol-treated vaccine containing active fixed virus; of these seven cases, five occurred in persons who had been treated with rabies vaccine previously. Pait and Pearson (1949), reviewing the experience of Los Angeles City and County from 1940 to 1946, found that there had been nine cases of severe postvaccinal reactions, including one death, among 5,500 receiving the vaccine, an incidence of 1:600 and a fatality rate of 0.018 per cent. It would be useful to know the risk of neuromuscular accidents associated with the use of each modification of the Pasteur treatment. The data available for this purpose are not sufficiently accurate and detailed to permit valid comparisons.

**IMMUNITY CONFERRED BY PROPHYLACTIC TREATMENT.** The immunity appears about two weeks after the treatment and lasts a varying period of time. In this respect it does not differ from other instances of acquired immunity. In one of Park's cases, it wore off in 14 months, the patient dying of hydrophobia after having been bitten a second time. The Pasteur prophylactic treatment, should, therefore, be repeated in persons bitten a second time. Marie found that dogs remained protected 18 months after treatment.

Immune bodies are demonstrable in the blood 20 days after the last injection. The activity of the virus can be neutralized by mixing it *in vitro* with the blood serum of an immunized animal.

**Contraindications.** There are no known contraindications to the treatment. All ages and conditions should be treated if exposed. Apparently no harm is done pregnant women. The treatment may be continued in patients having colds, fevers and other ailments without noticeable harm.

**TREATMENT FAILURE.** Since the introduction of the vaccine treatment, it has been apparent that the disease could not be prevented if the incubation period were short. For this reason, deaths occurring within two weeks of exposure to the bite of a rabid animal cannot properly be attributed to failure of the vaccine treatment. Indeed, one might take a more conservative view and regard only those cases which develop the disease two or more weeks following the completion of the treatment as failures, since maximum immunity cannot be expected before that time.

The most comprehensive data on deaths following antirabies treatment is that collected and published in a series of reports for the Health Section, League of Nations. In the tenth or last of these (Greenwood, 1945-1946), information is presented with regard to 228,051 treated persons, of whom 483 died of rabies. The crude percentage mortality was thus 0.21. The fatality rates are further analyzed by method of treatment and in relation to the more important variables: proportion of Europeans, species of biting animal, evidence of rabies in the biting animal, severity of bite, intervention of clothing, position of bite, delay in commencing treatment. These and other variables make interpretation of the data difficult and of limited value in assessing the failure rate of different modifications of the Pasteur treatment. While satisfactory scientific evidence of the efficacy of the different vaccines leaves much to be desired (Webster, 1942), the extremely low fatality rate among persons given any of the established methods of treatment has led to general acceptance of the concept that they afford a high degree of protection to individuals exposed to rabid animals unless the incubation period is short.

**INDICATIONS.** It is sometimes difficult to decide whether the Pasteur prophylactic treatment should be given. Treatment causes sufficient personal inconvenience, not to speak of the danger (however slight) of paralysis, to avoid advising it if unnecessary. In many cases it is impossible to discover whether the dog that inflicted the bite is mad or not. The rule is: in case of doubt advise the treatment.

Persons who apply for treatment of dog bites fall into one of the seven following categories with reference to the Pasteur prophylactic:

1. *The dog is mad; in this case, begin treatment at once.*

2. *The dog shows suggestive symptoms*: begin treatment at once; discontinue if diagnosis in the dog is established as negative.

3. *The dog is not mad*: observe it carefully for 14 days, and if no symptoms develop, there is no danger of rabies in the person bitten. The treatment is then unnecessary. (The dog may develop rabies after 14 days and if it has been bitten by another dog should be kept under control for at least six months.)

4. *The dog is not identified*: this is a common occurrence, especially with children. The rule in such cases is to advise the Pasteur prophylactic treatment, except in regions known to be free of rabies.

5. *Exposure to saliva*: persons not infrequently apply for advice giving the following history: They have not been bitten, but they have been licked on the hands and face by a dog that subsequently was discovered to have the disease. Persons are sometimes similarly exposed by washing the mouth of a rabid horse or cow. In these cases the important question is whether there were fissures or abrasions in the skin at the time. There may be little wounds in the skin not evident to the naked eye. It is possible to infect animals by rubbing the virus on the shaved skin. The rule is, therefore, to advise the protection which the treatment affords in persons thus exposed.

6. *In psychoneurotic patients* with a distressing phobia of rabies, it may afford comfort to give a mild course of treatment as much for its psychotherapeutic effect as for specific immunity.

7. *Fomites*: the question is often asked whether the disease may be contracted from contact with virus in saliva upon floors, on playthings and other objects. This situation arises with a rabid dog in the house, where children may be exposed in this indirect manner. While theoretically possible, the risk is negligible.

**Preventive Immunization of Dogs.** Practical requirements of the protective immunization of dogs are that the procedure be safe, that it confer a maximum degree of resistance for a long period of time and that it be administered in a single dose. A procedure which would seem to meet these requirements was introduced in Japan by Umeno and Doi (1921). It was used on a large scale and proved quite effective in the prevention of rabies in naturally exposed animals. The material employed was a fixed rabies virus vaccine, treated with phenol by modification of the Fermi method. It was administered by subcutaneous injection of a single dose of 5 ml.

This type of vaccine was used on a large scale in the United States during the period from 1922 to 1928. It was observed by Schoening (1925) that in extremely rare instances the vaccine could produce infection. This led to a ruling by the U. S. Department of Agriculture that rabies vaccine used for immunization of dogs must contain no active virus as determined by standard safety tests. To meet this requirement, commercial laboratories prepared a canine vaccine of the Semple type in which the concentration of brain tissue was 20 per cent. In a series of experiments, Leach and Johnson (1942) demonstrated that the chloroform-treated vaccine by Kelser when injected in dogs was found to produce a high degree of resistance to experimental inoculation. Furthermore, when stored for as long as 16 months at refrigerated temperature it still retained its immunizing capacity. The introduction of the mouse potency test led to further improvements of canine vaccines. Johnson (1945b) found that a single dose of canine vaccine of the

Simple type was an effective immunizing agent when tested in dogs and that immunity produced by a single injection of this vaccine persists for at least a year. Recently, there has been introduced a live vaccine for use in dogs prepared from a strain of rabies virus attenuated by passage in chick embryos (Koprowski and Cox, 1948). Experimental work suggests that it may confer a more durable immunity than that conferred by vaccines containing inactivated virus. From preliminary field trials, it appears that this avianized antirabies vaccine is safe and effective. Further trial is needed before judgment is passed.

**Rabies Control Procedures.** It has been demonstrated in many parts of the world that rabies can be controlled, even eradicated, in limited geographic areas by quarantine measures applied to the dog population provided wild animals are not involved in the propagation of the disease. Where rabies has once become established in wild life, as in the fox in certain eastern and coyotes in certain western parts of the United States, it has been possible to control the disease by reduction of the species affected. However, the principal reservoir in most parts of this country, as in others, is in dogs. Control depends fundamentally on measures which are directly or indirectly effective in reducing stray dogs to below the critical number required to maintain continuous propagation of the virus by passage biting. By the enforcement of ordinances designed to accomplish this reduction, rabies has frequently been temporarily eliminated from urban and suburban communities in this country. The disease has persisted in many rural areas, however, where the stray dog population is large and enforcement of control measures weak. Sooner or later, with relaxation of enforcement in the non-infected communities, an animal coming from the infected area starts a chain of transmission going again. It has not been possible to prevent such introductions by quarantine measures.

Demonstration of the value of preventive vaccination of dogs has afforded a new and extremely valuable additional means of control. By requiring mass vaccination of dogs, it is possible not only to reduce the proportion of strays but also to decrease the proportion of susceptible dogs in an area. This in turn decreases the chances of chain propagation. Vaccination of dogs, therefore, has become an important feature of the control program.

In a country as large as the United States, the problem cannot be settled by local action alone but requires nationwide cooperation.

It is currently recommended (Conference on Rabies, 1948) that the essentials of an effective control program are four: (1) recognition and definition of the responsibilities of local, state and federal agencies in dealing with the human and livestock phases of the problem; (2) adequate provision for diagnostic and treatment facilities; (3) provision for the immunization of dogs; and (4) legal authority, organization, personnel and facilities required for the control of animals capable of transmitting the disease. In connection with the latter, regulations should provide for the following specific measures in addition to requiring the annual licensing and vaccination of dogs:

- a. Proper disposition of ownerless, unwanted, and stray domestic animal pets.
- b. As soon as rabies appears in a community, strict control of all dogs should be enforced for whatever period of time may be considered necessary. Dogs should not be permitted to run at large but should be properly confined on their owner's

premises and only be permitted away from same when under proper restraint by a responsible individual.

c. Dogs which have bitten persons or other animals, and dogs which are suspected of having rabies, should be confined in a suitable, authorized place under veterinary supervision for a period of not less than 14 days.

d. Dogs known to have been exposed to rabies should be destroyed or kept confined for a period of not less than six months.

e. Dogs under six months of age, being particularly susceptible and less satisfactorily immunized than older animals, should be confined until the area is certified as officially free of rabies.

f. Adequate provisions and facilities for enforcing all regulations and requirements connected with the control program should be made available.

g. The control program should be continued for a period of at least 90 days subsequent to the last reported case of the disease in animals.

#### BAT RABIES

(*Derriengue, Mal de Caderas*)

The existence of rabies among vampire bats was recognized first in Brazil. In 1911, Carini reported the identification of Negri bodies in the brains of cattle dying of a paralytic disease called "mal de caderas." He also succeeded in infecting rabbits by the cerebral injection of brain material from paralyzed cattle. Ranchers had noted that bats were attacking and biting cattle in the daytime and that animals thus bitten died of "mal de caderas." This led Carini to suspect that vampire bats might be transmitting this disease. In 1916, Rehaag (Haupt and Rehaag, 1921) succeeded in isolating the virus from the brain of a bat. On the basis of this finding, Haupt and Rehaag concluded that the repeated epizootics of paralytic rabies that occurred among livestock in southern Brazil from 1913 to 1918 were due to rabies transmitted by vampire bats. The disease continued to spread and by 1930 had been found in Paraguay, Uruguay and Argentina to the south and up to the border of Venezuela in the north.

In 1925, a paralytic disease of livestock, including cattle, horses, mules, and donkeys, appeared in and around Port-of-Spain, Trinidad, B.W.I. During the period from 1925 to 1929 several thousand animals died of the disease, which was diagnosed as botulism. Hurst and Pawan (1932) proved by inoculation of laboratory animals the paralytic disease of livestock was due to infection with rabies virus. There had been no canine rabies in Trinidad since 1914. In 1936, Pawan reported the isolation of rabies virus from the salivary glands of vampire bats of the species *Desmodus rotundus murinus* Wagner captured in Trinidad. In another report, Pawan (1936) described the result of a study of rabies in naturally and experimentally infected vampire bats. One naturally infected bat proved capable of transmitting rabies by bite for a period of 56 days prior to its death, which was presumed to have been caused by rabies as Negri bodies were found in the brain. Vampire bats infected experimentally with rabies virus sometimes showed no signs of illness yet proved able to infect animals by bite. One of these bats was capable of transmitting rabies for a period of 83 days and subsequently died of the infection five months and 14 days after inoculation. The vampire bat is the only known host that can act as a carrier of rabies over an extended period with-

out apparent illness. de Verteuil and Urich (1936) reported an extensive study of the nature and habits of vampire bats and the epidemiology and control of vampire bats in Trinidad. Fifty-five human cases of paralytic rabies were recorded. The authors investigated 40 cases and found that with one exception there was a definite history of bat bite prior to the illness. The course of the disease in man is similar to that of canine rabies. Control measures included immunization of livestock with rabies vaccine, bat proofing of homes and stables, protective vaccination of persons bitten by bats and destruction of vampire bats. These measures proved successful in limiting the disease and no further outbreaks have been recorded in Trinidad.

Johnson (1948) studied a highly fatal paralytic disease of livestock called "derriengue" prevalent in the Pacific Coast states of Mexico. In the course of a field investigation conducted in 1944, in the states of Michoacan and Jalisco, seven localities were discovered where the disease had been prevalent in livestock in the previous six months. Vampire bats of the species *Desmodus rotundus murinus* Wagner were found in the immediate vicinity of each focus of the disease. Rabies were isolated from the salivary glands and brain of a paralyzed cow and from the salivary glands and brain of a vampire bat captured near one of the foci. The virus isolated from vampire bats is closely related to the known strains of rabies virus as shown by complement fixation and cross protection.

## RAT-BITE FEVER

(*Sodoku, Erythema Arthriticum Epidemicum or Haverhill Fever*)

A peculiar disease of man following the bite of a rat has been known in North America for a century or more. In 1839, Wilcox published an account of "Violent Symptoms from the Bite of a Rat." Modern interest was aroused by Miyake in 1900 of a clinical entity long familiar to laity and physicians of Japan as a rat bite disease or sodoku (from "so," a rat, and "doku," poison). It is a relapsing fever with an eruption. As a rule the initial wound heals cleanly. One to three weeks later the disease begins with the development of an angry, purplish indurated area at the site of the bite. The lymph nodes which drain the area become enlarged, tender and painful. The temperature suddenly rises to 103° or 104° F and remains high for one, two, or rarely, three days, then falls to normal for a period of from four to six days. Each succeeding week is characterized by a day or two of fever followed by five or six days of normal temperature. These paroxysms of fever continue for weeks or months unless interrupted by treatment. Between the paroxysmal attacks the patient feels quite well. The rash, which is irregularly maculopapular in character and dark red or purplish in color (morbilliform or rubellaform), develops on any part or over the entire body. It appears with the first or second paroxysm of fever and tends to disappear with the fall in temperature. Severe muscle pains and occasional joint pains are usually a feature at some stage of the disease. Ultimately the patient recovers, the case fatality being extremely low unless the disease is complicated by secondary infection.

**Etiology.** Futaki, and others (1917), by inoculation of white mice with material from local lesions, enlarged lymph glands and blood, recovered and identified a spirochete; they called the organism *Spirochaeta morsus-muris*. It was probably identical with *Spirillum minus* which had been discovered in the blood of a rat by Carter in 1887 in India. The latter name has received official sanction. The organism has not been grown in artificial culture media. For diagnosis, blood taken at the height of a febrile paroxysm, serum expressed from the margin of a rat-bitten wound, juice aspirated from a regional lymph node, serum expressed from the abraded surface of a prominent macule of skin rash or a macule excised from the skin should be injected either subcutaneously or intraperitoneally into a white mouse, white rat or guinea pig, or preferably all three. The blood of the inoculated animal should be examined daily in the dark field from the eighth to the fifteenth day after inoculation or longer. The biology of *Spirillum minus* in its relationship to rat-bite fever has been systematically reviewed by Robertson (1930).

Because of suggested analogies between rat-bite fever and syphilis, arsenicals were employed in treatment and have proved to be most efficacious. One or two

doses of salvarsan, arsphenamine or similar substances are usually sufficient to bring about a cure. In the United States, artificial induction of sodoku in the fever treatment of general paralysis was begun by Solomon and his associates in 1926 and was tried by others as a substitute for malarial therapy in this disease. By the inoculation of blood from infected animals into humans, typical disease was reproduced. Antibodies were demonstrated in the blood of all patients during their illness and in several instances the *Spirillum minus* was recovered from patients' blood by inoculation of guinea pigs.

Rat-bite fever, presumably caused by *Spirillum minus*, has been reported from widely scattered areas of the world. It is particularly prevalent where a large rodent population lives in close association with a dense human population, as in Japan and India. Bayne-Jones (1931) found records of 81 cases of this disease in man in American medical literature up to 1930. This list was brought up to 1940 by Brown and Nunemaker (1942) adding 40 additional cases. Critically reviewed, however, only 17 of the 125 cases had been carefully studied by animal inoculation. Although the bite of a wild rat is by far the commonest source of human infection, some cases are unable to recall any previous injury to a localized part. Other cases have been ascribed to such unusual causes as the bite of a cat, weasel, parrot, dog or bandicoot. *Spirillum minus* has never been found in the saliva of an infected rat. The infectiousness of a rat's bite has been explained as due to the escape of blood containing *Spirillae* from an abraded or diseased bucal mucosa to the biting wound, or by the contamination of the wound by conjunctival secretions. Secondary transmission of the disease from a sick individual to another human being is unknown.

In 1914, Schottmüller described a *Streptothrix* which he cultured from the blood of a patient suffering from rat-bite fever. Subsequently, other investigators had similar experiences. In 1925, Levaditi, Nicolau and Poincloux reported a case of "acute erythema multiforme" unassociated with rat bite, from which they cultivated a micro-organism which they named *Streptobacillus moniliformis*. In January 1926, a small but explosive outbreak of illness which occurred in a restricted area of Haverhill, Massachusetts, was carefully studied by Place and Sutton (1934). They called the disease "*Erythema arthriticum epidemicum*" or "*Haverhill fever*." Eighty-six persons were affected. The clinical manifestations of the disease were similar to those of rat-bite fever but differed in that there was no local lesion, multiple recurrences of fever were not found and arthritis was a characteristic feature. There were no fatalities. Epidemiological investigation established that the vehicle of distribution was a raw milk supply. There was apparently no spread by contact of patients with other persons. The manner in which the milk had been contaminated could not be ascertained. Parker and Hudson (1926) recovered an organism in blood culture taken from 11 of 17 cases, and fluid aspirated from knee joints in two cases. From its morphology and cultural characteristics it was ultimately identified as being *Streptobacillus moniliformis*. Milk is distinctly an unfavorable medium either for growth or viability of this organism.

While there have been no further outbreaks of this type recorded, investigators have continued to report sporadic cases of rat-bite fever from which they were unable to recover *Spirillum minus* by animal inoculation but were successful in recovering *Streptobacillus moniliformis* by the use of special culture media and

technics. The latter, or closely related organisms, moreover, have also been found to be naturally pathogenic in mice and rats. These observations have been carefully reviewed by Brown and Nunemaker (1942). They concluded that ratbite fever due to *Spirillum minus* and rat-bite fever due to *Streptobacillus moniliformis* could not be differentiated by clinical observations alone. In a more recent review, Watkins (1946) believes that the evidence justifies recognition of two diseases. He advocates that distinction be made between "spirillary" and "streptobacillary" rat-bite fever, and discusses in technical detail diagnostic methods of isolating and identifying both organisms.

**Prevention.** The occurrence of rat-bite fever, although inconsequential from the point of view of the morbidity it causes, is one more reason for the suppression of commensal rats about human habitations. Treatment with penicillin is promising (Altemeier and others, 1945).

#### LEPTOSPIROSIS

(Weil's Disease, Hemorrhagic Jaundice, Spirochaetosis  
Icterohemorrhagica, Canicola Fever)

During the latter part of the nineteenth century, it was observed that jaundice was sometimes the result of an infectious process. In 1886, Weil, on the basis of four cases which he had seen in Heidelberg, Germany, described the infectious disease which was known subsequently by his name. This condition has been, and still is, to some extent confused with epidemic jaundice or infectious hepatitis. Typically, Weil's disease is characterized by sudden onset with chills and fever, prostrations and muscular pains. About the fourth day jaundice appears in varying intensity and duration. There is an intense injection of the conjunctivae. Erythematous or papular rashes may occur. In severe cases there may be bleeding from the mucous membranes. Evidence of involvement of the kidneys is nearly always present and may progress to renal failure. Recovery begins in the second or third week. Relapse with a secondary rise in temperature lasting a week or more is not uncommon. The fatality rate, based upon cases with jaundice, is about 10 per cent. The period of incubation varies from 4 to 14 days, with a mean of about ten.

**Laboratory Diagnosis.** Investigating a disease endemic in certain parts of Japan which was similar or identical with Weil's disease, Inada and others (1916) discovered the cause to be a spirochete classified later as *Leptospira icterohemor-*

*rhagiae*. The micro-organism is recovered from the human cases by inoculation of young (200 gm.) guinea pigs or hamsters with blood obtained early in the course of the disease, or urine obtained somewhat later. Infection of a guinea pig is usually manifested by fever, loss of weight, and often jaundice. *Leptospira* are demonstrated in the heart's blood or in emulsion with the kidney or liver. They can be grown in special culture media at incubator temperature. Agglutination tests carried out with living or formalinized suspensions are valuable in confirming diagnosis. Demonstration of a significant rise in agglutination titers of paired early and late sera is evidence of the leptospiral nature of an illness. After recovery, specific agglutinins may be present in the blood for at least five years. The complement-fixation test is equally reliable for diagnosis (Gouchenour, 1952).

**Rodent Leptospirosis.** Studying the disease as it occurred in coal mines in Japan, Inada and others (1916) noted that patients were more numerous among the miners in wet than in dry mines. Clerks working outside the mines did not contract the disease. Experimentally, they demonstrated that leptospira were able to penetrate through skin even without local abrasion. They thought that infection might also occur through the alimentary canal. Although they had found that leptospira were excreted in the urine of patients during the acute illness and for some time after recovery, the distribution of cases did not suggest man to man transmission. Moreover, the disease did not occur in widespread epidemics. Following these studies, Miyajima reported that he found in *Microtus montebelli*, a vole, micro-organisms resembling *Leptospira icterohemorrhagiae* which when injected into guinea pigs produced fever and hemorrhage and, after a number of generations, jaundice. This suggestion led Ido and others (1917) to examine rats and they found virulent *Leptospira icterohemorrhagiae* in the kidneys in 40.2 per cent out of 149 *Rattus decumanus* and in *Mus* (*Rattus rattus*) *alexandrinus*. The micro-organisms cause little if any illness in rats. Entering by the mouth or skin, the leptospira localize in the kidneys and persist for weeks or months. Through excretion in the urine and contamination of food, soil or water, the organisms are transmitted from rat to rat and occasionally to other animals and to man.

The observations made in Japan were rapidly confirmed and extended by investigators in other countries. The frequency with which the infection was found in rats varied in different localities. For example, early surveys conducted in American cities revealed rates varying usually from about 10 to 40 per cent. Li and Davis (1952) found 45 per cent of 1,643 rats examined in Baltimore to be harboring these micro-organisms. In Amsterdam, 1923 to 1934, Schüffner (1934) found that of 515 adult rats, 26 per cent, and 313 young rats, 3 per cent were carriers of leptospira. Both the brown or Norway and the black rat, as well as mice, have been implicated; nor is the infection limited to these domestic rodents.

**Canine Leptospirosis.** In 1925, Okell, Dalling and Pugh, in England, discovered that canine jaundice, or "yellows" as it was known in dog kennels, was due to leptospira. Schüffner (1934) and his colleague Klarenbeek in Holland studied 50 dogs suffering from leptospirosis. Seventeen were found to be infected with *L. icterohemorrhagiae*, 28 were infected with a strain which could be differentiated by its serological reaction and by its pathogenicity. This dog strain was named *Leptospira canicola*. Meyer and others (1938) found this same strain of leptospira in dogs in California. It appears that dogs may be infected with either strain but observations thus far have failed to demonstrate *L. canicola* in rats. The pathology of

leptospirosis in dogs is similar to that in rats, the organism persisting in the kidneys and being excreted in the urine. The infection is not uncommon in the canine species. For example, Raven (1941) made agglutination-lysis tests on 105 dogs in rural Pennsylvania and found 38 per cent positive to either the rat or canine strain.

Human cases of infection with *L. canicola* have been described. For them the name "canicola fever" has been suggested. This disease is somewhat milder in its clinical manifestations than is the disease caused by the rat strain (Rosenbaum, 1946).

**Other Leptospira.** A number of other serological races of leptospira have been recovered from human and animal sources. The most important of these is *Leptospira grippo-typhosa*, the cause of the nonicteric clinical syndrome known in eastern Europe as swamp fever and in other places as summer influenza, harvest fever, mud fever, and water fever. The animal reservoir of this leptospira is unknown. Another variant *Leptospira hebdomadis* is the cause of epizootics in voles and of a "seven day fever" in Japan. These variants have not been identified in the United States. *L. biflexor* is a nonpathogenic species sometimes found in stagnant water.

**Human Leptospirosis.** Leptospirosis is world wide in distribution. By 1939 it had been reported from 46 countries. In western Europe and the United States human infection with *L. icterohemorrhagiae* from association with rats or dogs is by far the most common form, but occasionally human infection with *L. canicola* is encountered. Molner and others (1948) reviewed American literature and listed 228 cases of human leptospirosis. As clinical awareness has increased and as laboratory diagnostic methods have been more commonly employed, it has become apparent that human leptospirosis is much more prevalent than was formerly thought. In the milder forms of the disease the jaundice may be transient or absent. This is particularly true of "canicola fever." The clinical manifestations are reduced to an acute onset with chills, fever, pains in the limbs, headache, conjunctival injection, stiff neck, and recovery within a week or 10 days. These nonicteric cases escape recognition unless diagnostic laboratory tests reveal their identity. Intensive studies, such as that of Ward and Turner (1942) in Baltimore, are enlightening. Serological examination of 91 employees of nine poultry dressing establishments for agglutinations of *L. icterohemorrhagiae* revealed 13, that is, 17.3 per cent positive. The sera of three out of 48 meat packers were positive. Of 234 blood sera collected from patients in the Johns Hopkins Hospital and the Baltimore City Hospitals, 21 were found positive; only eight of these were from patients on whom the clinical diagnosis of Weil's disease had been made.

**Occupational Selection.** While leptospira die rather quickly when exposed to sunlight and drying, they will live for a period longer than three weeks in stagnant water which is neutral or slightly alkaline. Human cases of leptospiral infection arise from two general sources. The first group comprises persons whose occupations demand working in wet, rat infested places. So it has been noted to occur particularly in miners who work in wet mines, sewer workers, tunnel diggers, cutters and cleaners of fish, workers in abattoirs, poultry dressers, etc. Courts in England, Germany, and the United States have awarded compensation for Weil's disease as an occupational hazard (Stiles and Sawyer, 1942). In similar manner, infections

with *L. canicola* have been found in veterinarians and persons who live or work in intimate contact with dogs.

A second group originates from submersion or swimming in contaminated water or drinking it. In Amsterdam and other cities in Holland a considerable number of cases have been attributed to submersion by accident or with suicidal intent as well as to bathing in the water of canals which are polluted by human and animal refuse and whose banks are infested with rats. Havens and others (1941) reported an instance in which seven young men who had been swimming in a pool adjacent to rat-infested cattle barns came down with attacks of leptospirosis from 4 to 12 days later. Ward and Turner (1942) reported two cases in the same family due to drinking water from a contaminated well.

**Prevention.** Ordinarily, the disease is sporadic in occurrence. When a case occurs every effort should be made to ascertain the source of the infection and to prevent other cases arising from the same source. While community measures for the suppression of rat populations are desirable under any circumstances, efforts to effect rat control should be intensified on premises where there is an occupational hazard. The wearing of protective clothing such as waterproof boots and gloves is expedient where indicated.

Although patients may continue to excrete leptospira in the urine for some weeks after recovery, no special measures of isolation are necessary. The risk of transmission to attendants and familial associates is apparently negligible. Appropriate antibiotic therapy promises to shorten the duration of the infection.

#### CHORIOMENINGITIS

(Acute Lymphocytic Choriomeningitis)

Armstrong and Lillie (1934) described a previously unidentified virus encountered during studies of brain material from an individual who died in St. Louis, Missouri, during the 1933 epidemic of St. Louis encephalitis. Two additional strains

of a similar virus were described by Armstrong and Wooley in 1935, one of which was isolated during studies of the brain of an individual who died in Maine, and the other from a monkey that died following inoculation with the virus of poliomyelitis. About the same time, Traub (1935) recovered a virus from his experimental stock of white mice that resembled that described by Armstrong, and expressed the opinion that the mouse was probably the natural host of the virus. Rivers and Scott (1936) reported the isolation of similar strains from two human cases of illness diagnosed as aseptic meningitis. The strains of animal and human origin were subsequently shown to be identical serologically. Additional evidence establishing the causal relationship of this virus to human disease was contributed by Lépine and others (1937) who demonstrated that by subcutaneous injection of the virus from mice, the symptoms of aseptic meningitis could be induced in human beings and the disease transmitted from man to man by means of intramuscular inoculations of infected blood. These observations were confirmed and extended by investigators in many parts of the world.

**Human Infections.** The incubation period is uncertain, but it is thought to vary from one to three weeks. The onset is sudden, frequently with respiratory and constitutional symptoms similar to those of influenza. In many patients, the illness terminates after a few days without further complications. In others, with or without a remission of fever, the first phase is followed by definite signs of meningeal involvement with headache, vomiting, stiffness of neck and photophobia, which may endure for about two weeks. Complete recovery is the rule. In the occasional case, the infection progresses to the development of definite encephalomyelitis, with mental changes, aphasia, diplopia, and paralysis. Deaths are rare. The virus can be recovered from the central nervous system and from the lungs of patients dying of the disease. The infection may occur without recognizable symptoms or as an inapparent infection.

**Laboratory Diagnosis.** When there is clinical evidence of involvement of the central nervous system, the cerebral spinal fluid shows an increase in lymphocytes up to 3,000 cm. The nature of the etiologic agent can be established by recovery and identification of the virus or by serological tests. The agent may be obtained from blood or cerebral spinal fluid early in the disease. The suspected material is inoculated intracerebrally in mice. Precautions should be taken to insure that the mice used are from a stock which is itself virus free. Guinea pigs or mice may be tested as early as the fifth or sixth day after inoculation for complement fixation with hyperimmune serum (Smadel and Wall, 1941). The virus may be propagated in tissue culture and in 11- or 12-day-old chick embryos. Serologic evidence of etiology is obtained by testing acute and convalescent phase sera for complement-fixing antibody or neutralizing antibody. The second specimen, or convalescent serum, should be collected about three weeks after the onset of illness for complement-fixation test, and about 6 to 10 weeks after onset for neutralization tests.

Acute lymphocytic choriomeningitis cannot be diagnosed by signs and symptoms alone. The nature of the illness can only be established by laboratory procedures. These are necessary in order to differentiate it from similar clinical syndromes associated with the arthropod-borne encephalitides, poliomyelitis, mumps, and other virus infections.

**Infection in Mice.** Laboratory stocks of apparently healthy mice in all parts of the world are liable to suffer from natural infection. The presence of LCM virus must always be excluded when any new viral agent is isolated by mice. Further, the virus may be passed in series unknowingly, along with another agent as a laboratory contaminant. Mortality in infected mouse stocks is less than 2 per cent. Most animals show no symptoms, although the virus is present in the blood, brain, urine, and nasal secretions. Most of the animals developing evidence of the infection, such as emaciation, drowsiness, and ruffled fur, are young, from two to six weeks old.

A mouse stock in which lymphocytic choriomeningitis was endemic was observed over a period of four years by Traub (1939). The disease persisted during this period but became so mild that it could no longer be recognized by clinical observation. In spite of this fact, all of the stock mice tested, both young and old, carried considerable amounts of virus in their organs and blood. The females readily transmitted the infection to their offspring. Intra-uterine infection became the only mode of transmission of the disease in contrast to the situation at the beginning of the observation, when a certain number of mice were born virus free and became infected by contact shortly after birth. The virus seemed to be almost perfectly adjusted to survival in mouse colonies.

Evidence that in nature gray mice, *Mus musculus*, are the natural reservoir for LCM virus was developed by Armstrong and others (1940). Gray mice trapped in the homes of four different patients were demonstrated to be active carriers of the virus. In their investigations in Washington, D. C., 52 per cent of the mice in homes in different sections of that city were found to be harboring choriomeningitis virus.

**Occurrence.** The method of transfer of the virus from mouse to man has not been definitely established, although infection through dust or food contaminated by mouse droppings seems likely. Wooley and others (1937) demonstrated antibodies by the protection test in 11 per cent of 1,248 human sera tested. These sera were obtained from inmates of federal penal institutions and from beneficiaries of the U. S. Marine Hospital. Eighteen per cent of 481 adults over 17 years of age, but only 1.2 per cent of 396 persons under 17 years of age, were positive. The occurrence of demonstrable antibodies in 117 sera from 997 individuals without history of central nervous system or meningeal involvement, suggested that immunity might result not only from the frank meningeal attack but also from either subclinical infection or a clinical condition, possibly an upper respiratory complex, not recognized as due to choriomeningitis. Since the virus of LCM was first identified, in 1934, it has been isolated in several localities in the United States, England, France, Japan, and there is evidence pointing to its presence in Africa and Ireland. It seems probable that it is world wide in distribution.

**Prevention.** Prevention of infection of human beings with LCM virus depends upon cleanliness in food preparation and storage and suppression of mouse infestation on domestic and occupational premises.

## PSITTACOSIS

(*Ornithosis, Parrot Fever*)

Psittacosis as a disease of man was first brought to attention by Ritter's classical description of a small outbreak of "pneumotypus" at Uster, Switzerland, in 1879, at the home of his two brothers. The parrots incriminated in this outbreak were recently imported from Germany. Numerous outbreaks have been reported subsequently, the most extensive being the Paris epidemic of 1892 and the 1929-30 prevalence which invaded many countries.

Nocard studied dead birds connected with the Paris outbreak and isolated an organism, *Bacillus psittacosis*, a member of the *Salmonella* group, which he described as the causative agent in 1893. His observations were confirmed and generally accepted, and *B. psittacosis* has been isolated several times from birds and once from a human case of psittacosis at autopsy. However, during the 1929-30 outbreak independent observers, Bedson, Western and Simpson; Pesch; Krumwiede, McGrath and Oldenbusch; Armstrong, McCoy and Branham and others showed that psittacosis is caused by a filter-passing agent, a virus, which has been recovered from both birds and man.

Man usually contracts psittacosis through contact with sick birds, although apparently healthy birds may be carriers and transmit the disease. Under certain conditions this infection is extremely contagious from birds to man and is especially prone to attack those working with the experimental disease in the laboratory. Yet it is a frequently confirmed fact, first observed by Ritter, that psittacosis is but slightly communicable from man to man. At the Hygienic Laboratory in 1930, not a single contact case developed among some 200 persons variously exposed to the 11 human cases of this outbreak. A careful study of this epidemic indicates that the trouble was air-borne. The virus could readily be sent into the air when parrots preen and then shake their feathers and flap their wings.

The disease tends to appear in household outbreaks in which the case fatality rate may vary from 0 to 100 per cent. In large series of cases it usually varies from 20 to 40 per cent. There are few deaths in persons under 30 years of age, since in children and young adults the disease tends to be mild. Infection occasionally follows parrot bites or close contact, such as mouth-to-mouth feeding, but in most instances the mode of transmission is obscure.

Psittacosis has most often been confused with influenza, bronchopneumonia

or typhoid fever. Its onset is usually sudden with chilliness, fever and headache. Focal pneumonia usually becomes established during the first days of symptoms when the x-ray reveals a faint, usually circular, cloud of uniform density, situated oftenest in one of the lower lobes, with physical signs. The pneumonic spot may remain localized but in severe cases tends to spread upward while fading below and may involve the opposite lung. Cough and expectoration are usually absent or slight early but may become troublesome later. Sputum, when present, is most tenacious and difficult to expel. The tongue as a rule presents a heavy white coat, and abdominal distention is a frequent and troublesome symptom. Albuminuria is common after the first week and retention may be present; "rose spots" are occasionally noted. Leukopenia is usual during the height of the ailment. Relapses are not infrequent. Phlebitis is the commonest complication. One attack apparently confers immunity in the parrot and rabbit, but there are practically no direct data bearing upon the immunity conferred by the disease in man.

**Virus.** In the past decade, considerable progress has been made in characterizing the virus which causes psittacosis. It belongs to a group of viruses including the infective agents of lymphogranuloma venereum, meningo-pneumonitis, murine and feline pneumonitis. The group is characterized by the formation of intracellular inclusion bodies which may be seen in the infected tissues—LCL bodies of Levinthal, Coles, and Lillie. They are minute coccobacillary bodies arranged singly and in pairs, bearing a resemblance to rickettsiae and to Paschen bodies. The LCL bodies usually have a diameter of from 300 to 400  $\mu$  and are held back partially or completely by filters which allow most viruses to pass. This group of micro-organisms, therefore, appears to be intermediate between the viruses and the rickettsiae. They are readily propagated in the yolk sac of embryonated hen's eggs. Excellent antigens suitable for complement-fixation tests may be obtained by ether-chloroform extraction of yolk sac cultures. The complement-fixation test does not distinguish between the psittacosis and the lymphogranuloma agents. Mice are susceptible to infection with all members of the group when inoculated by the intranasal route and, with some, by the intraperitoneal route. Cross protection tests conducted on mice disclose strain distinctions. Manire and Meyer (1950) developed a toxin-neutralization technic with antiserum produced in chickens by hyperimmunization, on the basis of which 27 infective psittacosis agents were arranged into 6 separate and distinct groups.

The host range of psittacosis virus has been considerably extended by observations made during the past few years. Of particular importance is the implication of infection in pigeons and barnyard fowl, chickens and ducks. Table 9-3 shows the sources of cases of psittacosis in the United States from 1945 to July, 1950.

**Control.** Efforts to prevent the occurrence of human psittacosis have been principally directed toward restrictions on the importation and interstate shipment of psittacine birds by federal regulations, and restrictions placed upon breeding establishments, aviaries and pet shops by state and local regulations. These have been amended from time to time. Foreign quarantine regulations, effective December 15, 1951, provide that "Psittacine birds shall not be brought into the Continental United States, its territories or possessions (other than the Canal Zone) from any foreign country or from the Canal Zone." Three exceptions are made:

under prescribed conditions birds may be brought in for purposes of medical research, exhibition in zoological parks and by an owner if they do not exceed two in number (Federal Regulations, 1951).

Table 9-3. Sources of psittacosis in the United States, 1945 to July, 1950

\* One patient died.

† Two patients died.

Restrictions on interstate transportation have been removed except that any shipment of psittacine birds must be accompanied by a permit from the health department of the state of destination, where it is required. State regulations vary greatly. In California, it has been demonstrated that with the application of scientific knowledge, psittacosis can be eradicated in parakeet breeding establishments, provided adequate funds are available for laboratory tests, for rigid supervision and for compensation of owners called upon to sacrifice their infected flock. However, even in this state where vigorous and apparently effective protective supervision of bird breeding establishments was enforced for many years, while there was a progressive reduction by control measures, new foci of infection appeared from time to time in spite of all precautions. The importation, breeding, sale, or offer of sale of birds of the psittacine family was prohibited in New York State and in New York City in 1938, but these regulations were revoked in 1952. This action was justified in part by the following considerations: Human cases are so few in number that psittacosis is a minor public health problem; effective antibiotic therapy is now available; the discovery of widespread reservoirs of the virus in other bird species, pigeons, domestic ducks and chickens, etc.; lastly, practical difficulties or impossibility of enforcing these interstate quarantine regulations. There is a question as to whether there is justification for the elaborate and expensive administrative provi-

sion necessary to supervise bird breeding establishments. Principal reliance must be placed on educating and continuously warning the public and physicians to appreciate the danger from contact with birds which may be shedding psittacosis virus.

The beneficial effects of penicillin, aureomycin, and terramycin on acute human psittacosis have been established. In birds, the antibiotics merely suppress multiplication of the infective agent but do not terminate the carrier state. The hope of ultimate control of psittacosis by eliminating avian carriers through the use of antibiotics has received little encouragement.

### COCCIDIOIDOMYCOSIS

(*Coccidioidal Granuloma, San Joaquin or Valley Fever*)

This disease was first described in Argentina by Posadas and by Wernicke in 1892 and ascribed to a protozoan-like organism found in the tissues of the patient. In 1896, Rixford and Gilchrist gave an account of a protozoan (coccidioidal) infection of the skin and other organs in two patients who were farm laborers working in the San Joaquin Valley of California. They named the spherical organism which they observed in preparations from the tissues of the patients *Coccidioides immitis*. Following this publication, similar cases were described by other physicians in southern California, and the disease became to be known as coccidioidal granuloma. Ophüls and Moffitt, in 1900, demonstrated that the causative agent was not a protozoan but a pathogenic mold, and Ophüls, in 1905, succeeded in isolating the organism in pure culture and reproduced the disease in animals.

**Coccidioidal Granuloma.** In that region, coccidioidal granuloma became known as a chronic, progressive, highly fatal fungus disease, affecting the lungs, skin, lymph nodes, bone meninges, thoracic viscera, and other body tissues, and resembling tuberculosis in many of its aspects. Beck collected from the literature reports of 286 human cases of chronic coccidioidal granuloma. Of these, 254 occurred in California and 16 in other states. It soon became evident that most of the cases had resided in, or had traveled through, the southern half of the Great Sacramento (San Joaquin) Valley of California.

**Diagnosis.** Investigations which were conducted during this period led to the development of procedures which were of great value in identification of the infectious process (Smith and others, 1950). It was found that an antigen prepared from broth cultures, coccidioidin, was extremely useful in demonstrating allergy

to *Coccidioides immitis* by a skin test and in indicating the presence of antibodies in the serum of patients by precipitin and complement-fixation tests. Finding and identifying the causative organism in sputum, pus or tissues provided the conclusive diagnosis. A tentative identification may sometimes be accomplished by cover slip examination of suspected material, but such findings should be confirmed by cultural recovery and examination. *C. immitis* grows readily on Sabouraud's glucose agar at room temperature, but more useful differential media are now available. After four to six days' incubation, a flat membranous type of colony appears which in the course of the next week becomes covered with an abundant cottony aerial mycelium, which is at first snow white and then becomes tan brown. Microscopic examination of young cultures shows branching septate hyphae, which later fragment into numerous thick-walled rectangular, ellipsoidal or spherical arthrospores about 2.5 to 3 by 3  $\mu$  in size. These arthrospores are detached easily by jarring or shaking the culture, and numerous laboratory infections have resulted from the inhalation. This spore is the infectious form of the micro-organism. The tissue phase (spherules) has rarely been observed in artificial culture. The suspected culture should be injected into mice or guinea pigs to confirm its characteristic pathogenicity.

**San Joaquin Fever.** For at least 50 years there had also been endemic in the San Joaquin Valley a disease known as San Joaquin fever, valley fever, desert fever, or desert rheumatism. Characteristically, the illness consisted of influenza-like initial phase followed in from 2 to 18 days by an eruptive phase of erythema nodosum, less frequently of erythema multiforme, frequently associated with arthritis and conjunctivitis. The eruption lasted from six days to two weeks, and as the lesions faded pigmented areas remained for months. Recovery was practically invariable. Between 1936 and 1938, Gifford (1942) and Dickson (1938) established that this clinical syndrome was in fact the benign acute phase or primary stage of coccidioidal granuloma. Dickson suggested that the various manifestations of infection of man and animals with *C. immitis* be called coccidioidomycosis. Infection with the coccidioides fungus was thus clinically manifested in at least two ways, i.e., (1) by a primary acute infection of the respiratory tract, often accompanied by erythema nodosum from which the great majority of patients recover in a short time without complications; and (2) by a later more or less chronic granulomatous secondary phase, known as coccidioidal granuloma, which is very disabling and has a high case fatality rate.

These observations were confirmed and extended by the field studies of Charles Edward Smith (1940). Using the coccidioidin skin test, it was found that a large proportion of individuals living in the southern San Joaquin Valley reacted to this antigen, while only a small fraction gave a definite history of having suffered from erythema nodosum. Skin sensitivity to coccidioidin was demonstrable in 2 to 17 days after onset of symptoms, generally during the second week of illness. The evidence developed by observations on accidental laboratory exposures and field studies indicated that the infection might be manifested by a mild, indefinite, influenza-like attack without skin eruption or even occur without identifiable symptomatology as an inapparent infection.

**Frequency of Clinical Manifestations.** Military studies made during World War II in the 4th Army Air Field in the San Joaquin Valley of California, permits

an estimation of the frequency of the different manifestations of the coccidioidal infections (Smith, 1947). At one extreme is a completely asymptomatic or inapparent infection. Such an infection can be demonstrated only by conversion or changeover from a negative to a positive coccidioidin skin test. In the southern San Joaquin Valley, approximately 60 per cent of natural infections fell into this category. Even under conditions optimal for diagnosis, only one fourth of the infections produced clinically diagnosed disease. Around 4 per cent of infections in white males, and 10 to 25 per cent of the infections in white females were accompanied by erythema nodosum or multiforme of the classical valley fever. Approximately one in 400 coccidioidal infections, or one in 100 cases of diagnosed disease in white adult males showed the progression known as coccidioidal granuloma. The frequency of this granulomatous dissemination in Negroes was 10 times that of whites.

**X-Ray Findings.** If x-rays of the chest are taken during the acute phase of a moderately severe attack, dense shadows will usually be found in the hilar regions, indicating enlargement of the hilar glands. Radiating from the hilar region, and more widely distributed through the lung area, are densities indicating parenchymatous involvement of the various parts of the lung. These may appear in all lobes. Tuberculosis is often suspected upon the first examination but later the areas of increased density gradually decrease until in a few weeks they disappear. Occasionally, a patient with such pulmonary shadows has been sent to a sanatorium for tuberculosis when it was impossible to prove tuberculosis by recovering acid-fast bacilli or by tuberculin test. If the disease goes into the secondary progressive granulomatous stage, evidence of pulmonary cavitation may develop. The association of pulmonary calcification with healed coccidioidal infections has been recognized for some years (Cox and Smith, 1939).

**Occurrence.** One of the interesting contributions of World War II investigations was better recognition of the coccidioidal endemic areas in the United States. In California, it has been shown that, although the most highly endemic area is San Joaquin Valley, in Tulare and Kern counties, exposure to *C. immitis* is not limited to this area. Spotty endemic areas were discovered on the north extending as far as Merced County, southwest into and over the coastal range to Santa Barbara and Benventura counties and to the south and southwest in San Diego, San Bernardino and Riverside counties. To the east of California the endemic area embraces parts of the southern tip of Nevada, southwest Utah, southern and central Arizona, western Texas and southern New Mexico. Coupled with the knowledge that merely driving through an endemic area can result in infection, means that the disease must be considered in differential diagnosis by physicians in the western states and, indeed, by physicians practicing anywhere in this country.

Field studies of the endemic area of southern California indicate that newcomers rapidly acquire the infection. For example, as the result of an extensive coccidioidin testing program in Kern county schools, Gifford (1942) found that over one half of 2,718 children gave positive reactions, the percentage rose progressively from 17 per cent with Kern county residence under one year to 77 per cent with residence of 10 years or more. Although military personnel were passing through Minter Field rather rapidly in 1941 and 1942, 0.5 to 5.0 per cent of the susceptible persons were infected each month (Smith and others, 1946). The seasonal variation is related

to climate and rainfall. Maximal incidence was realized from July through October, when it was dry and dusty. Incidence is minimal through the wet winter months.

**Sources of Infection.** Clinical and pathological evidence establishes the respiratory tract as a portal of entry in nearly all cases of human infection. Rarely are cases encountered in which *C. immitis* gains entrance to the tissues through contamination of a wound. Observations on experimental animals and accidental laboratory infections have established the fact that the infective forms of coccidioides are the arthrospores. There is no evidence of transmission from man to man or from animal to animal under natural conditions. The question of where the fungus multiplies and the arthrospores originate has not been settled. The fungus has been repeatedly recovered from soil samples. Emmons (1943) has suggested that certain wild rodents, notably pocket mice, may become infected and die, and in their carcasses the mycelia develop from the spherules (sporangia) of the parasitic or tissue phase. Dogs, sheep, and cattle have also been found to be naturally infected (Stiles and Davis, 1942). Possibly other animals may harbor the fungus.

Whatever the source may be, it is apparent that in the endemic areas the minute arthrospores of the vegetative phase are widely distributed in nature. Dust is apparently the natural vehicle of dissemination. When susceptible human beings stir up dust in a highly infected area veritable epidemics occur.

**Prevention.** Avoidance of the risk of coccidioidal infection in endemic areas is an unsolved problem. Apparently, the vast majority of human beings who live in these areas gain immunity very quickly through benign natural infections of short duration. Under the special conditions which prevail in army camps in coccidioidal areas where large numbers of susceptibles are being introduced, and those infected are departing as fast as they become immune, measures directed toward local dust suppression may be warranted (Smith and others, 1946). Wherever feasible, grassing should be used. Surfacing of roads and, to a limited degree, of athletic areas is important. If turf cannot be maintained on these areas, the application of a highly refined oil may be tried. However, one should first examine the character of the soil. If the soil is a fine loose silt, success is unlikely. If it is a heavy adobe type, the procedure is more effective. Such measures, however, are not practical in a civilian community of large extent. As yet no specific drug is available for treatment.

## HISTOPLASMOSIS

Between 1906 and 1909, Dr. Samuel T. Darling, pathologist in the Panama Canal Zone, described three cases of a fatal human infection resembling miliary tuberculosis somewhat but caused by a parasite, for which he proposed the name *Histoplasma capsulata*. His report received little attention until 1926, when a case of histoplasmosis was discovered in Minnesota by Watson and Riley. Subsequently, there were reports of cases from various localities. The studies of De Monbreun in 1934, and of others, demonstrated that the causative organism was a fungus which could be easily grown on artificial culture media of appropriate composition. It was established that histoplasmosis was essentially a systemic infection with this small yeast-like fungus. As the organism grew in various reticulo-endothelial tissues of the body, nodules were formed which tended to coalesce and caseate, producing extensive areas of necrosis, ulcers and abscess cavities.

Clinically, the disease is characterized by a gradual onset accompanied by marked evening rise in temperature, pain, either generalized or localized in the abdomen, chest, back or joints, and with gradually developing asthenia, anorexia, and loss of weight. On examination, patients might show enlargement of the liver and spleen, generalized or regional enlargement of the lymph nodes, generalized or localized abscesses or ulcers of the skin, lung abscess cavities resembling tuberculosis. Roentgenologic chest films show characteristic, persistent pulmonary infiltrations. In the advanced stage, a wide variety of symptoms are present, depending upon progression of the infection in different organs. Parsons and Zarafonetis (1945), in a review of the 71 cases which had been reported up to that time, found that the disease had been fatal in most instances. In more than four fifths of the cases the duration of symptoms averaged five months. In three cases the infection appeared to have lasted for 8, 10, and 16 years before ending fatally. Four patients were still living after intervals of two to six years. More recently, Furcolow (1950) has presented pertinent clinical and laboratory data on 16 additional cases which have been carefully studied. His case material shows variation in diagnostic certainty ranging from clear-cut, uncomplicated cases of clinical histoplasmosis, through the probable cases to those in which the finding of *Histoplasma* was incidental to the diagnosis of another disease. Of the 16 cases which he studied, five have recovered; two other cases are still classed as ill.

**Portal of Entry.** The portal of entry of the fungus is still unknown. The large number of patients who have ulcerated lesions of the mouth, pharynx and gastrointestinal tract suggest that the entrance is through the alimentary canal. There are, however, many cases in which lesions of the nose, pharynx, larynx, and lungs are present, suggesting that the respiratory tract may also be a portal of entry. Another smaller group of cases suggests entrance through the skin.

**Diagnosis.** Diagnosis is confirmed by demonstrating the organism in preparations of materials from the tissues or from sputum. *H. capsulatum* grows readily on blood agar slants at 37° C if the tubes are sealed after inoculation, and on Sabouraud's glucose agar at room temperature. It is killed at 55° C in 15 minutes and by 1 to 2 per cent formalin in 24 hours. In 1941, Van Pernois and his colleagues and Zarafonetis and Lindberg introduced the use of an intradermal test for diagnosis

of *H. capsulatum* infection. The antigen was prepared from a filtrate of a two to seven month old broth culture. In low dilution the test is not specific. Cross reactions have been demonstrated with antigens prepared from other fungi such as blastomycin, coccidioidin or haplosporangin and from *Candida albicans* (Cross and Howell, 1948). The reaction occurs within 24 to 48 hours after intradermal injection. An area of redness and edema 0.5 cm. or more in diameter is regarded as positive.

A complement-fixation test for histoplasmosis has been developed (Furcolow and others, 1948) which is more specific and dependable for diagnosis.

**Relation to Pulmonary Calcification.** Studies made in certain sections of the United States in the decade 1935 to 1945, revealed that the prevalence of pulmonary calcification was far beyond that which could be explained on the basis of tuberculosis as indicated by the tuberculin test (Gass and others, 1943). At first the view was advanced that this phenomenon represented the reversion to negative of a once positive tuberculin test. As reports accumulated, however, it became evident that the prevalence of this unexplained pulmonary calcification had a strikingly uneven geographic distribution. It was peculiarly prevalent among young people living on, or adjacent to, the western Appalachian plateau, or on the eastern slope of the Mississippi River basin and the bordering states of the western slope of the Mississippi River, i.e., the Eastern Central States. Its prevalence varied not only from state to state within the area, but some striking differences were demonstrated in counties within the state. This suggested that some condition other than tuberculous infection was responsible for this calcification.

Christie and Peterson (1945) explored the hypothesis that pulmonary calcification in tuberculin-negative persons was due to histoplasmosis. A preliminary study of chest roentgenograms and skin sensitivity to histoplasmin and tuberculin of 181 children from middle Tennessee revealed an interesting correlation between histoplasmin sensitivity and pulmonary calcification. This finding was confirmed and extended by Palmer (1946) who, on the basis of a study of the histoplasmin reactions of 8,141 student nurses, demonstrated that an area of high prevalence of positive histoplasmin reactors existed where tuberculin-negative cases of pulmonary calcification are most frequently found, in the Mississippi Valley states, including Tennessee, Kentucky, Arkansas, Mississippi, Indiana, and parts of Ohio, Illinois, Kansas and Louisiana, although the condition was far from rare in many other regions.

**Geographic Distribution.** Mochi and Edwards (1952) have reviewed the available information on the geographic distribution of (a) clinically recognized histoplasmosis and (b) of histoplasmin sensitivity. The highest rates of histoplasmin sensitivity in any region of the world have been found in the east-central part of the United States. In Canada, histoplasmin sensitivity has been found only in the southeastern provinces. A somewhat lower rate of reactors has been reported from scattered localities in Mexico, Central and South America. Practically nothing is known concerning sensitivity in Asia, except for two investigations in India which revealed a negligible number of reactors. Observations made in most European countries have failed to demonstrate any sensitivity areas, although single isolated cases of histoplasmosis have been diagnosed in Austria, Bulgaria, England, the Netherlands, Portugal, Spain and Turkey. Several cases occurred in the Union of

South Africa, which appears to be an area of low prevalence of sensitivity, but little is known of the rest of the African continent.

**Sources and Conditions of Transmission.** How man acquires the infection is not clearly understood. *Histoplasma capsulatum* has been recovered from a number of animal species: mice, rats, dogs (Emmons and others, 1955), cats, horses, skunks, opossums, woodchucks and foxes. The fungus has been repeatedly recovered and identified from soil and dust in localities associated with human cases and it has been demonstrated that spores of *H. capsulatum* can survive in the soil for several years. It has been suggested that inapparent animal infections are responsible for soil contamination. But thus far the extrahuman source of multiplication has not been identified (Emmons, 1950). The circumstances under which groups of human cases have occurred, together with the characteristics and localization of lesions in the pulmonary area, strongly suggest air-borne infection resulting from the inhalation of spores in the dust of the atmosphere (Grayston and Furcolow, 1953; Loosli and others, 1954). Thus, human infection is incidental, a terminal side chain, in the natural survival propagation of *H. capsulatum*. There is no specific drug therapy.

## TOXOPLASMOSIS

GILBERT F. OTTO, Sc.D.

Toxoplasmosis is an infectious disease concerning which relatively little is known beyond its fatal course in infants. The biology, means of transmission, and even the systematic position of the causative agent is largely undetermined. *Toxoplasma gondii* is usually accepted as a protozoan, and frequently is classified with the malaria parasites among the *Sporozoa*. The multiplication by longitudinal binary fission, however, suggests a closer relationship to the flagellates so that many prefer to group it among those forms of unknown systematic position. The organism is an intracellular parasite of the cells of the reticulo-endothelial system but develops in the syncytium of the central nervous system, the parenchyma cells of internal organs, and has been found in the circulating leukocytes, and even erythrocytes.

The individual organisms are from three to six  $\mu$  in length, range in shape from round to slightly crescent-shaped spindles; usually one end of the spindle is broader and more blunt than the other giving it a piriform appearance. There is a large conspicuous nucleus in the center. Multiplication is by binary fission and repeated multiplications may completely fill the host cell, leaving only its membrane intact. The resulting accumulation has been called a cyst, pseudocyst, terminal colony, and has even been mistaken for a schizont. Upon rupture of the host cell membrane, the parasites may be found free in the blood or interstitial fluids. The organisms have not been grown on lifeless media but in tissue culture the dividing forms are suggestive of the leptomonad stages of the *Leishmania*.

Although the parasite was first discovered in birds and rodents in the tropics,\* most of the recognized human cases have occurred in the temperate zones of the United States and Europe. To what degree this is a reflection of the actual distribution of the human infection and to what degree it is merely a reflection of better differential diagnosis is not clear. The total number of clinical cases reported in medical literature scarcely exceeds 50. Although prenatal infection is the explanation offered for most, if not all, of the fatal cases in infants, and the cases of congenital chorioretinitis, it puts a heavy strain on credulity to believe that this is the only, or even the principal, means of dissemination in nature. Speculation runs the gamut from air-borne and feces-borne to arthropod transmission.

The infection has been found in a wide variety of birds and animals. Specific names have been given to the various forms from different hosts but so far there is no evidence to support the concept of different species, and considerable evidence against it. The forms are morphologically and immunologically indistinguishable one from the other, so far as they have been tested. Fatal epizootics have been reported in canaries and wild birds in Germany and among rabbits in the Dutch East Indies. *Toxoplasma gondii* has been found in birds, rabbits, and dogs in Brazil, and appeared spontaneously in a guinea pig colony in Panama. It has been found in birds, cats, and rats in the United States. In one survey in Savannah, Georgia, 9 per cent infection was found in wild rats.

Only in the severe, usually fatal, infections have the parasites been demonstrated

\* Apparently, it was first seen by Laveran in 1900 in paddy-birds in Java and first ascribed (as *T. gondii*) by Nicolle and Manceaux in 1908, from a small rodent (the *gondi*) in North Africa.

in man. The fatal cases of toxoplasmic encephalomyelitis in infants have been characterized by convulsions, hydrocephalus, cerebral calcification, and chorioretinitis. In toxoplasmic encephalitis of older children, who were presumed to have acquired the infection after birth, neither hydrocephalus nor chorioretinitis occurred. In two adults, an acute fatal exanthem with pulmonary involvement suggesting typhus fever has been described.

The uncertainty of direct microscopy or of animal inoculation in antemortem diagnosis has led to the development of several intradermal and serological tests. Using Sabin's neutralization test, Heidelman (1945) found antibodies in 17 of 27 children with congenital chorioretinitis and in six of seven mothers of such children. No more than 10 to 15 per cent of normal adults taken at random or children with pathological conditions of the eyes, other than chorioretinitis, gave positive reactions. Surveys in various parts of the United States, using Sabin's more recently developed "Methylene Blue Test" (Sabin and Feldmann, 1948), have suggested that the infection is widespread and in some cases even more than 10 per cent of the population may have circulating antibodies.

Since the usual method of transmission is unknown, it is impossible to offer intelligent suggestions for prevention. Unfortunately, no effective therapeutic agent is known. Therapeutic testing on experimental animals (Weiman and Berne, 1944) has not revealed anything more promising than the sulfa drugs, sulfapyridine and sulfadiazine.

#### TREMATODE DISEASES

WILLIAM W. CORT, Ph.D., Sc.D.

**The Parasites and Their Life Cycle.** The trematodes that infect man may be divided on the basis of the location of the adults in the human host into liver flukes, intestinal flukes, lung flukes, and blood flukes. Only the blood flukes, or schistosomes, have a world-wide importance in disease production. The trematode diseases are very rare in North America, but with increasing contact with their endemic areas in other parts of the world the danger of their introduction into the United States has become a significant public health problem. This danger was forcibly brought to the attention of health authorities by the infection with oriental schistosomiasis of large numbers of American soldiers in the Philippines during World War II. Except for the blood flukes, the larval stages of which penetrate the skin from water, infection is from ingestion of encysted stages with food. In fact, in some cases, rather unusual food habits are involved.

The trematodes (class Trematoda) are flat worms belonging to the phylum Platyhelminthes which also includes the tapeworms. All the human forms belong to

the subclass Digenia which are internal parasites, having a very complicated life cycle involving an alternation of generations and change of hosts. The adult stages which are parasites of vertebrates, are either hermaphroditic or bisexual (schistosomes) and produce eggs which pass to the outside. The larval stage that develops in the egg (miracidium) can only continue its development in a molluscan intermediate host. The miracidium may either hatch in the open and penetrate the surface of the body of the intermediate host, or it may hatch after the egg is ingested and penetrate the wall of the digestive tract. It establishes itself in the lymph spaces of the snail and metamorphoses into the primary germinal sac (the mother sporocyst) in which the embryos of the next generation develop. These become secondary germinal sacs which, in all the important trematodes of man, except the schistosomes, have a pharynx and intestine and are known as rediae. In the schistosomes the secondary germinal sacs are elongate sacs without any trace of a digestive system and are known as daughter sporocysts. The final products of the daughter sporocysts or rediae are cercariae, the bodies of which develop directly into the adults in the vertebrate host. The development in the intermediate host provides for the production of large numbers of individuals to meet the hazards of transfer to the final host. The cercariae of all the trematodes that infect man are free-swimming and have tails. All except the schistosomes have an encysted stage (the metacercaria) which may occur either on vegetation, or other surfaces, or in the tissues of second intermediate hosts. The schistosome cercariae are able to penetrate directly the skin of the final host and have no encysted stage or second intermediate host.

**Liver Flukes.** *Clonorchis sinensis* is the most important of the liver flukes of man. Its normal habitat is the smaller bile ducts of the liver, but in heavy infections it has been found in the large bile ducts and the gallbladder, and in a few cases in the ducts of the pancreas. This parasite can develop in a number of different mammals besides man, including the dog, cat, and pig. Infection of the final host comes from the ingestion of the encysted stages in raw or improperly cooked fish. Almost 50 different species of cyprinid fish, a number of which are used as human food, have been reported as second intermediate hosts of *Clonorchis*. The snail intermediate hosts are operculate snails belonging to the subfamily Bithyniinae.

The injury produced in the final host by *Clonorchis* is centered in the liver. The development and activity of the worms in the small bile ducts produce a very great hypertrophy of their walls which, in heavy infections, interferes seriously with liver function. A large proportion of cases show no noticeable symptoms, because the host is able to compensate for the damage produced by the small number of worms that are present. In heavy infections, however, the extensive damage to the liver produces a long standing chronic disease, the chief symptoms of which are epigastric pains, diarrhea, edema and ascites with anemia, and jaundice. Extremely heavy cases are sometimes fatal.

The endemic areas of clonorchiasis are limited to the Far East, and it is especially prevalent where dishes containing raw fish are commonly eaten. The worst endemic area is in northern Indochina (Tonkin and Annam), with the highest incidence and severest disease in the delta of the Red River in central Tonkin. This parasite is also a significant health problem in south Korea and south China (Kwantung Province), and has a widespread but rather localized distribution in Japan. Although numerous individuals infected with *Clonorchis* are known to have entered

the United States over a period of many years, there is no good evidence that it has ever become established in this country.

Studies in Japan suggest that much of the infection with *Clonorchis* comes from the eating of improperly cooked fish. In Indochina and south China popular dishes containing raw fish have been implicated. In south China it has been shown that fish raised in artificial ponds are heavily infected (Faust and Khaw, 1927). They are shipped to Canton and other centers of population and are used in popular raw fish dishes.

Certain gold preparations, antimony compounds, and gentian violet have been shown to have some action against these parasites, but much further work is needed to put the treatment of clonorchiasis on a really satisfactory basis. On account of the widespread distribution of the snail intermediate hosts, and the number of domesticated and wild animals that harbor this parasite, the only practicable control method appears to be the prevention of human infection from the eating of raw or insufficiently cooked fish.

*Opisthorchis felinus* has been known for many years as an incidental parasite of man in eastern Europe. More recently, it has been found to be widespread and important in the production of disease in certain areas of the U.S.S.R., particularly in the valleys of the Irtysh and Ob rivers in eastern Siberia. Its life cycle and disease relations are very similar to those of *Clonorchis sinensis*.

*Fasciola hepatica*, the common liver fluke of sheep and cattle, has been known as an incidental parasite of man for many years. Well over 300 human cases of infection with this parasite have been reported in the literature from different parts of the world. Since the encysted stages occur on grass and other vegetation, on any surfaces exposed to water containing the cercariae, and even on the surface film of the water, human infection might be produced in a variety of different ways. The eating of wild water cress from bodies of water to which sheep or cattle have access has been suggested by several authors as a method of human infection. *F. hepatica* produces a very serious disease of sheep, and in some of the human cases severe symptoms have been present. Most human cases, however, appear not to have been very serious due probably to the small numbers of worms present. The use of copper sulphate to kill the snail intermediate hosts has proved to be a very effective method of controlling this parasite.

**Intestinal Flukes.** *Fasciolopsis buski* is the most important of the intestinal trematodes of man. The adults live in the small intestine of man and the pig. Like *F. hepatica* this trematode has no second intermediate host, and infection comes from the ingestion of the metacercariae that have encysted on the surface of water plants that serve as food for the definitive host. The snail intermediate hosts are small planorbids that live on vegetation in shallow ponds or other small bodies of water.

The severity of the disease produced by this parasite depends primarily on the number of worms that are present. Epigastric and hypogastric pains and a diarrhea, often severe, that tends to alternate with constipation, are the commonest symptoms. In heavy infections edema appears rather early and ascites is a common symptom. Untreated cases with large numbers of worms are often fatal, death apparently being due to a general toxemia.

*F. buski* has been reported as very widely distributed in the Orient. Over most

of its range it appears to be much more common in the pig than in man, although a few human cases have been reported from a number of different places. In China, there exists in northern Chekiang province a very important endemic center of this parasite where in an area of about 1,600 square miles, more than a million and a half people are infected with a large proportion of severe clinical cases. Barlow (1925) studied the epidemiology of this disease in this area and concluded that its prevalence was due to the cultivation of "water nuts," chiefly the water caltrop, *Trapa natans*, in shallow artificial ponds. These ponds are ideal habitats for the snail intermediate hosts; the eggs of the parasites are introduced in enormous numbers by the fertilization of the crop with "night soil"; and the cercariae encyst on the surface of the "water nuts." The peeling of the "nuts" with the teeth when they are eaten raw appears to account for most of the infection.

Since *F. buski* lives in the lumen of the small intestine, it is rather easily removed by a variety of anthelmintics. Barlow outlined control methods involving killing the eggs in the "night soil" by chemicals or storage, mass treatment, and attempts to modify the food habits of the people.

A large number of other species of trematodes belonging to several different groups have been reported as intestinal parasites of man. Most of them are forms which are common in other mammals and occur in man either in very limited areas or as incidental parasites. Most of these parasites appear to have little, if any, significance in the production of human disease. An exception has been demonstrated by the recent work of Africa and his co-workers (1940) in the Philippines. They found that the eggs of certain small trematodes of the family Heterophyidae that are incidental parasites of man may get into the general circulation and produce serious lesions in various organs, chiefly in the heart muscles. They concluded that these parasites were responsible for a considerable proportion of the heart disease in the patients in the hospitals in which they made their studies. In 13 cases where death was attributed to heart conditions they considered that the lesions produced by the trematode eggs were the primary cause of death. These studies open up a whole new field for further investigations, and give us a new concept of the possible importance of incidental human infection with trematodes.
